Such is the construction of the Gülcher lamp; it now remains to be seen how the peculiarities of its arrangement render it suitable for being used in groups, in the same circuit, and how an economical distribution of the current is secured. The first and second of the regulator of the third, and so on. This regulating action depends on the positive motion of the electro-magnet G, upon the quantity of current passing through the circuit. To take first the simple case of two lamps put in parallel circuit with the generator. If a lamp be first lighted by connecting the branch wire from the terminal of the electro-magnet to the main conductor from the positive pole of the generator, the light will established itself as has been already described, then if the connection with lamp 2 be completed the current is divided, and lamp 2 is lighted. At first the part of the current which passes through lamp 2 is stronger than that passing through lamp 1, because the carbon points of the latter are in contact, and the resistance is less. The result of this inequality is that the electro-magnet of lamp 2 is set in motion, the carbons are separated, and the resistance is increased, at the same time that this takes place, the current passing through lamp 1 is strengthened, and the carbons are brought nearer together. A closer inquiry From this it will be seen that if in either lamp the carbons become too far separated, the increased strength of current in the other will tend through the action of the magnet to draw down its carbon-holder, increase the distance between the points, and so weaken the current in the first-named lamp, that the magnet will cease to maintain the carbon-holder, which will allow it to fall till equilibrium is established, or the same process is reversed, and so on, one lamp regulating the other, and consequently itself. With three lamps in parallel circuit as shown in Fig. 3, the same processes take place; when all three are lighted, lamp 1 regulates lamp 2 and 3, lamp 2 regulates 1 and 3, and lamp 3 regulates 1 and 2.

No. 3 regulates 1 and 2, and No. 3 regulates 1 and 2.

Mr. Gülcher claims in his patent specification that these lamps, when constructed of special mechanisms can be used for the division of the electric light by means of a single arrangement in parallel circuits. The advantages of a good arrangement of parallel circuits, and the application in connection with it of strong quantity regulators (in opposition to the division of the electric light hitherto attained by currents of high tension and differential lamps placed one after another) of great importance, and consist essentially in the following: That the electric light produced by this process is thoroughly white (without the violet or bluish tints in light produced by currents of high tension); that the number of lamps which can be fed by a single source of electricity is nearly unlimited; that the power used by the dynamo-electric machine is proportional to the number of lamps which are in use, thus are fed by it; that greater number) can be provided for by one and the same machine; and finally, the lamps can be attended to whilst at work without any danger, and even the current with recovered portions of the conducting wires by unprotected parts of the body is free from danger." It must be admitted that the experience gained at the Paris Electrical Exhibition, and recently at Messrs. Bateman and Co.'s, with the Gülcher lamp go far to sustain the greater portion of these claims.

The manner in which Mr. Gülcher arranges his conductors for working a number of lamps on the same circuit we reserve to the end of this article. Knowing the number of lamps to be fed and the distance of the furthest lamp from the source of power, he ascertains the cross section of the main conductor required to transmit the total current. He then constructs a cable having the same number of strands as there are lamps in the circuit, and each of such a diameter that the total cross section is equal to the required area of the principal conductor. This cable is then laid from the positive pole of the battery, one strand being branched off to the first lamp, another to the second, and so on for the whole number, till at the last lamp the final strand is connected. In the same manner the return conductor commences with one strand at the first lamp, and gradually becoming a strand at a time with each lamp returns to the negative pole of the generator with the same number of strands as left from the positive pole leaves it. Following Mr. Gülcher's explanation of the arrangement of the conductors it will be seen that each separate circuit to each lamp is of equal length, and the cross section of each conductor corresponds exactly with the strength of current flowing to it. If S be the area of the cable of conductors leaving the generator, s the area of each wire forming the cable, and n the number of lamps, as the total current is equal to the sum of the branch currents of equal strength, $S = ns$; consequently the current flowing to the $(n-1)^{th}$ lamp $= s(n-1)$, and so on. Thus in an installation of twelve lamps arranged in three rows of four, each row having $\frac{1}{3}$ branch current as $S = \frac{1}{3}s$ in this case $S = 12s$, and the cables leaving and returning to the generator are made up of twelve wires. Judging from the experience gained with the Gülcher system, it seems called upon to play an important part in electric illumination.

To conclude this notice we may give the summary of some recent trials made by Mr. Gülcher. They consist of a series of measurements of the electric current and resistance of the lamps and of the power they absorb. In these trials are also included some relating to the internal resistance and the electromotive force of the dynamo-electric generator of Mr. Gülcher which we have described above.

The first Table shows the lighting power obtained with a given intensity of current. The trials were made with a Gülcher generator feeding six large lamps on one circuit. The generator was driven at a speed of 640 revolutions a minute, and the intensity of the standard photometric lamp was exactly 1 carcel. The following ten measurements were taken, the photometric values being on the horizontal plane of the arc.

method of collecting and distributing election returns by small gauge way to the employment of special couriers these in turn were superseded by the telegraph, and now the telephone is called into requisition to meet the demands of this fast age. Had any one asserted a few years ago, that a gubernatorial candidate could receive complete returns through the medium of the human voice, while seated in his own residence, and afterward receive the congratulation of his friends and supporters in distant sections of the State by personal conversation with them at their residence, he would have been regarded as a fit candidate for the lunatic asylum.

THE ELECTRIC LIGHT.

WORCESTER, MASS.—The electric light plant at Worcester will probably be completed by Nov. 15. When finished a local company will be organized to operate it.

PITTSBURGH, PA.—The Brush lamp has hitherto had a monopoly of electric lighting in Pittsburgh, but a movement is now on foot to organize an Edison electric light company in that city.

THE STEAMER WESTERSLAND.—The fine large, new Red Star steamer Westerland is now on her way from Antwerp to this port. The Siemens Brothers have fitted her up with their electric lights.

"THE RISKS IN ELECTRIC LIGHTING."—An electric light pole on Park Avenue, Baltimore, took fire one day last week, it is supposed from one of the wires, and the fire department had to be called upon to extinguish the flames.

NEW CORPORATIONS.—New local electric light companies are reported as follows: The Circleville Edison Electric Illuminating Company, of Circleville, O.; capital, $25,000; and the Gem City Electric Lighting and Power Company, of Quincy, Ill.; capital, $60,000.

[illegible] Electric Company is the [illegible] [illegible] [illegible]

St. Louis, Dec. 1883.

AMERICAN TRADE JOURNAL.

Edison's Electric Light.—The Decline in His Company's Stock.

Among the unlisted securities, few are so little traded in now as the electric light stocks. This is doubtless almost wholly due to the unfortunate experience of those who bought these stocks at fabulous prices when they first came on the market, and have since seen them go comparatively speaking, almost out of sight. Of course the Edison companies, and their stock bonses, made the market for this class of securities—and ruined it again also. A one hundred dollar share of the Edison Electric Light Company once sold on the street at $4,000. The same stock can now be purchased for $170, and the well informed doubt if it is worth even the latter small sum. Were it not for the prestige of Edison's name, which gave the stock its first boom, but could not save it from its final collapse, the stock would probably have no regular market price. It has never paid a dividend, and were it not for the auxiliary companies, which are simply construction and manufacturing companies, we doubt if it could pay its expenses. The light furnished has fallen below the expectations of the company's partisans, and is regarded as a failure by the disinterested. An inspection of its light in many of the buildings where it has been introduced will satisfy any one that it is far inferior to the light supplied by two or three other companies whose names are not to be seen in the public. Less than 20 per cent of the tenants of the Mills Building are said to be using the Edison light, and from no lack of desire on their part for a superior light either. The other evening we were invited by a friend to view his handsomely appointed office into which he had just moved—the principal feature of which he hoped would be the electric lights. He must have been greatly disappointed, however, for although there were a half dozen illuminating wires in each cosy room, in our judgment a chandelier hung in the centre of each, with a similar number of jets, would have given a more satisfactory light. We do not believe that electric lighting generally is a failure. Indeed, we see ample evidences in various offices that it is being successfully used; but Mr. Edison must either perfect his system soon, or consumers will have to look to other companies for their light.—[*New York Daily Stockholder.*

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 8689.

SATURDAY, SEPTEMBER 29, 1883.

CONCERNING ELECTRICITY.

An article in the *North American Review* over the signature of Edison, confirms our editorial remarks, made on the 10th of July last, respecting the true condition of his system of electric illumination.

The course of Edison has been consistent, and from first to last he has emphatically stated that the results arrived at last January practically demonstrated the success of his system for the ends in view, and that nothing remained to be done but to improve his lamp and generator, to bring both to as near a state of perfection as a long series of exhaustive experiments would permit.

Of course, Edison has also had to master the enormous mass of details incident to the practical working of his electric lamp on a large scale for general use, and that he has accomplished both tasks within a year must be a matter of astonishment to all who have any conception of the work done; but Edison seems born to overcome difficulties that appall other men, and the fertility of his mental resources appears unbounded.

In the discussion of scientific questions affecting vested interests, impartial treatment and justice to the innovator are lost sight of. Better things, however, might have been expected from some of those who have misled the public in regard to this matter. Under the belief that Edison's electric lamp was a failure, thousands of dollars have been lost by those who have invested their money in electric light companies which have tried to force systems of lighting, fundamentally wrong in principle, and ridiculously unfit for general illuminating purposes.

There is one fact which places the sincerity of Edison above reproach; he has the assurance of his system of electrical illumination to assert its own supremacy with the public, and has neither paraded his light in great cities, nor gone on a lecturing tour, as other eminent inventors have done; and lastly, he has spent thousands upon thousands of dollars in perfecting his system.

On his system of electric illumination Edison has staked his time, money, and reputation. He now states that he has succeeded. Let those who are wise accept the situation.

The series of equations afforded by XIV. and XV. will be employed in solutions of inscot supports and tunnel rings, when a similar course—acoplet or quadrangular in arrangement, that may hereafter be given.

LITERATURE.

Cotton Spinning: a Practical Treatise. By Hermann Ewerdan Tatlock. London: Simpkin, Marshall, and Co., and Sun. London: Simpkin, Marshall, and Co., 1883. This literature of the cotton trade has always been unsatisfactory. When the subject has been treated scientifically the result has seldom been of any use to the ordinary spinner, and when it has fallen into the hands of practical men, the information has usually been a set of empirical rules, which, although probably suitable enough for the conditions under which they were compiled, had no range of application, and gave no clue to the theory upon which they had their basis. Every few years an enterprising overlooker, with a taste for arithmetic, presents the public with a volume filled with problems worked at full length, relating to the calculation of twist wheels, counts, &c., and—no doubt such a book is useful to his fellow workmen in the same district, who from a limited education find it easier to follow a formal example than to apply the explanation of a principle to a particular case. But Mr. Watson's plan of something higher than this; at least, so we gather from his preface and his introduction, in both of which his remarks are addressed to those who aspire to the position of managers to cotton mills. To such he gives very good advice, urging them to be "acquainted perfectly with every detail of the whole business," and to devote their whole energy to the one object of learning the business thoroughly, both practically and theoretically." From the above recommendation we expect to find the subject treated in such a way that its underlying principles may be understood, while at the same time the practical details upon which those principles depend are kept prominently to the front. Instead of this, however, we find the first part devoted to short descriptions of machines, most of which would be satisfactory enough if addressed to a visitor going through a mill from curiosity, but of no value to the manufacturer; while, in cases where greater detail is entered into, the remarks apply only to the productions of Messrs. Platt Brothers, and consequently are meaningless in a mill furnished by another firm. The next chapter is devoted to "calculations" of the usual style, with simple propositions some within the capacity of "half-timers," given at full length. If this were the only charge to be made against these rules, it would be a very serious matter, but most of the rules lie under the further disadvantage of having to be learned by rote unless the reader is acquainted with the theories upon which they are based, in which case they are unnecessary. For instance, "To find the twist wheel in changing from one hank to another" we are told to "square the present twist wheel, then multiply result by present hank rove, divide by future hank rove, extract square root of quotient, and you get twist wheel required." This simply means that the number of teeth in the twist of change wheel must vary as the square root of the count or hank rove of the yarn being spun, the reason being that the number or counts of cotton yarn are not, like the wire gauge, a measure of the diameter, but of the cross section, and therefore, as the twists per inch vary as the diameter, they consequently vary as the square root of the counts. Half a dozen lines of explanation, such as this, would fix the matter in the mind of the reader in such a way that it would never be lost, while the rule by itself is sure to be forgotten. This is true of most of the directions given, but a good many are also incorrect, as well as insufficient. For instance, the speed of the throstle spindle can not be found by "multiplying the speed of the front rolls by its circumference and dividing the result by the diameter of the bobbin," while there is certainly something wrong about the following calculation. "A 20-in. bolt is moving at a rate of 2000 ft. per minute, with 0 ft. of its length in contact with the circumference of a 4-ft. wheel. What will be its horse-power? $20 \times 12 = 1440 \div 3 = 2000 = 1,440,000 \div 30,000$ worked = horse-power = 123 1.11." It would not be difficult to find a dozen glaring errors of the kind, but we must push on to the last portion of the book, of which we are pleased to be able to speak better. It is composed partly of workshop receipts and spinning-room dodges, and partly of specifications of machinery, apparently from Messrs. Platt's practice, and from the style in which it is written leads to the conclusion that the author is dealing with subjects with which he is familiar. A rather odd list of "Odlums counts" indeed the whole historical evidence of the book, especially the author's belief in the supporting influence of water in cotton yarn, points to its having been written in Odham. It is a pity that coming from a place where the cotton manufacture is carried on in the greatest perfection, this work should be so far behind the requirements of the times and the promises of its preface.

A Rudimentary Treatise on Clocks and Watches and Bells. By Sir Edmund Beckett, Bart., LL.D., Q.C., F.R.A.S., &c. Seventh Edition, revised and enlarged. London: Crosby Lockwood and Co., 1883.

This was one of the first of the rudimentary treatises undertaken by the late Mr. Weale, and the fact that it has run through six editions, and that a seventh is now issued, is evidence of the appreciation of the public, or at least of that portion of them that take an interest in clocks, watches, and bells. As regards clocks the work teaches the principles of horology, and as much practical knowledge as may be useful both to clockmakers and to amateurs. That part which deals with watchmaking, an art which depends greatly on handicraft skill, is confined to a consideration of principles only, while the chapter on bells is stated to be the only English treatise on their proper construction, their hanging, and the best method of hanging.

The work commences with an account of the various measures of time, explaining the difference between mean and apparent time, the equation of time, and the like. Then, after a brief historical portion, the next hundred pages are devoted to pendulums and escapements, after which three chapters are given to the going and striking parts of clocks. Church and turret clocks receive a great deal of attention, and are evidently a favourite subject with the author. He tells at considerable length the history of the Westminster clock, and of the disputes that were waged about it from 1846 to 1856.

Under the heading of watches and chronometers all the chief compensating balances and the various escapements are described, and some useful hints are to the subject of bells, in which he has had a great experience, having designed, in addition to the Westminster peal, many others for different parts of the country.

It is needless to add anything in way of commendation of this work, which has long stood as a standard authority. The genuine enthusiasm of the author for his subject, and his immense stock of information, are to be discerned on every page, and explains why he has taken interesting ranging even to those who have hitherto paid little regard to the exact measurement of time.

THE BRUSH INCANDESCENCE LAMP.

(*Concluded from page* 483).

The most important requisite in incandescence lighting is a good lamp, and at the same time it is the most difficult to obtain. This is evidenced by the fact, that while there are numerous reliable lamps known in the market, only one lamp (the Swan) has come into extensive use in this country. Even the Edison lamp, with all its good qualities, and the lavish expenditure that accompanied its introduction, has made but little progress here. A report issued by the French company, dated March, 1883, gives a list of all the installations of the English company, and the total number of lamps does not amount to 9000, a surprisingly small record. Hence news of the points claiming the most attention of the Brush Company was the recognition that they were working on the elaboration of a system that would produce lamps of regular and uniform quality, of great endurance, and endued with a capacity for sustaining a high degree of incandescence. Abandoning the loose-hoop, first advocated by Mr. Lane-Fox, they adopted prepared carbon thread as the material of their filaments, following in other respects the general lines of Mr. Fox's plan. But it is well known that the efficiency of an incandescence lamp depends to a great extent upon the extent to which it is made, than the skill and care expended upon its manufacture, and the perfection with which the air and occluded gases are removed from the globe and conductors. The general features of the Lane-Fox process of making incandescence lamps are now carried out as well understood and needs only brief mention. Cotton thread is wound upon a block of carbon of pear-shaped section, and after being packed with powdered graphite in a crucible is exposed to a red heat for a considerable time. After it has become cool the thread is broken into lengths at the point where it was bent over the sharp edge of the block, and each piece, after it has been cut to the desired dimensions, serves as the filament of a lamp. It is necessary first, however, to reject all those whose resistance exceeds certain limits of divergence from a given standard, and this is determined by sending a current through each while in circuit with a galvanometer. The mounting of the filaments upon the platinum conducting wires and the whole of the evaporatory work is done by gas, and it is only in the sealing, exhausting, and flashing processes that men are employed. The adjustment of the lamps to a standard resistance, so that all may give the same light under similar conditions, is done at two operations, the first bringing them nearly to the required point, and the second making the final reduction. Each filament is placed in a bottle through which a stream of hydro-carbon gas is passing and is connected to two leads maintained at a constant potential, while momentary currents are sent through it by means of a key, flashing it into incandescence and depositing the carbon of the gas upon it, particularly at the hottest points which attain the highest temperature. When the resistance is brought nearly to the standard, the filament is mounted in its globe, the conductors sealed into their places, and the necessary process of adjustment is repeated with a more delicate measuring apparatus until the exact required resistance is attained.

The exhaustion is effected by the Lane-Fox air pump, which is very simple and gives a high vacuum, but at the same time entails a good deal of manual labour, as the mercurial reservoir has to be raised another high at each stroke, and the escape valve opened and closed by hand. After the vacuum has been formed a current is sent through the lamp to drive out the occluded gases, and the pumping is renewed from time to time over a considerable period, until it is seen that there is no discharge whatever. The lamp is then sealed up at the exhaustion tube and separated. It remains, however, to provide terminals for the conducting wires, and for this purpose a screw cap is employed, the cover cut by a wooden plug, is slipped over the neck of the globe and secured by Portland cement. The ends of the conducting wires are brought through holes in the plug, and twisted round the terminal screws, which then are made to form contact-pieces to which the positive and negative mains must be connected.

As in the Swan and Edison systems, so in the Brush system, the act of fixing the lamp in its holder or socket establishes the necessary electrical connections. The socket is convolved in shape, and is designed to fit the cover of an ordinary gas bracket at its lower end, while at the top (Fig. 1) its points or pedals exert an elastic pressure upon the globe that prevents any vibration. The two leading wires are led up the centre of the holder and are secured to two separated pieces of metal fixed to a non-conducting plug in the body of the socket. When the lamp is dropped into position, and the bayonet joints of the bracket, and the bayonet joint (Fig. 1), the holder of the incandescent lamp, and lower (the above-mentioned curved springs, forcing them down towards the plug, by which they are attached at one end, and making a good contact, which is retained even after the time the lamp is removed or inserted. Figs. 2, 3, and 4 show the socket constructed in a more substantial manner for attachment to a wall or a piece of furniture. In Fig. 3 the lamp is replaced by a plug provided with flexible wires for connection to a portable bracket or counter, and fitted with terminals similar to those upon a lamp neck. Fig. 5 illustrates Grindle's ancient socket, which has been used by some of the Brush subsidiary companies. This has no bayonet joint, but is provided with a set screw to fix the lamp, while the contact springs are set in a vertical position instead of a horizontal one, the terminals of the lamp being correspondingly modified in accordance. By rotating the lamp 90 deg. the electrical connections are broken.

In Fig. 6 there is shown a Brush incandescence

The generating apparatus of the Maxim system, like the Siemens and Gramme alternate current machines, as well as the dynamo-electric generators of M. Lontin, consists of two distinct machines (1) an electric generator whose magnetic field is produced by powerful electro-magnets, and whose current is utilised in the lamp circuit, and (2) a smaller machine on the dynamo-electric principle, the current from which is employed exclusively for exciting the field magnets of the large machine. The Maxim system has moreover, in addition to these, a third form of apparatus to which we have already briefly referred, viz., a current regulator by which the strength of the current in the lamp circuit is automatically controlled and adjusted to the number of lamps in action.

The Maxim machine which we illustrate by Fig. 4, p. 611, bears (on account of the disposition of its field magnets, and the arrangement of its magnetic field) a remarkable resemblance in general appearance to the small Siemens exciting machine used for the alternate current generators, or to one of the large Siemens machines set up on end so as to place its magnet helices in a vertical position. The machine, however, differs entirely from the Siemens machine in the construction of the rotating armature, which, instead of being in the form of a solid cylinder (as in the Siemens machine), is built up of a number of separate coils, each of which is wound upon a bobbin having its various wire sections arranged over its cylindrical ring or tube, like a ring wound either in the form of a series of longitudinally inside but outside the ring as in the Gramme armature, of which the Maxim armature is in fact a modification, but it differs from the Gramme armature in the fact that the length is considerably greater than its diameter, in other words, that it is rather in the form of a tube than of a ring. It also differs from the ordinary Gramme armature in having two of the coils and the armature are connected alternately to the commutators, that is to say, as the wire sections were numbered consecutively 1, 2, 3, 4, &c., all the even numbers are connected with one commutator and the odd numbers with the other. The Maxim armature is in physical principle a combination of the Gramme and Siemens machines, and may, in that sense, be described generally as a Gramme armature working in a Siemens magnetic field, but it has, in constructive detail so many points of originality, as to give to it a separate and distinct position among electric generators.

Referring to the engraving, Fig. 1—which represents the principal machine connected up as a dynamo-electrical machine, exciting its own magnets, and requiring, therefore, no separate exciting machine—it will be seen that the field magnets consist of two sets of iron bars of rectangular cross section, surrounded at the upper and lower ends by rectangular coils of insulated wire, which are so connected together that the currents traverse them in series, and in such directions as to produce a line of North polarity along the middle of one set of curved iron bars, and a similar line of South polarity along the corresponding middle line of the opposite set of bars, thus producing an intense magnetic field between them, within which the armature cylinder is rotated at a speed of about 900 revolutions per minute. This armature consists of a quantity of soft iron wire coiled into the form of a cylindrical tube about 16 in. long and about 12 in. in diameter, and wound after the fashion of a Gramme ring with a set of sixteen sections or helices of insulated copper wire, each helix consisting of four wires, the ends of which are connected to the sixty-four sections of the commutator. The system of winding, as well as the disposition of the electro-magnets, is best shown in the illustration of the smaller machine, Figs. 3 and 4, the ring and those of the large machine, but the armature of the large machine differs from that of the exciter in the fact that its contiguous coils are connected to different commutators, eight coils being attached to the commutator at one end of the shaft and the eight alternate and remaining coils being coupled to the other, so that the ring may be regarded as two armatures in one, each producing a distinct set of currents, which by a very ingenious contrivance of switching arrangements, as will be seen in Fig. 7, can be united either in parallel

FIG. 2

circuit or in series. Referring to the latter figure this switching apparatus consists of four pieces of copper, differing entirely from the Siemens machine in the figure, while at M, N, and P are represented insulated pieces of ebonite, into which conducting pegs can be inserted when required. On each of the brass pieces A, B, C, and D is a binding screw, which can be connected by conducting pegs in P, B is connected to the machine's own parallel circuit, can be arranged to supply a dynamo machine for a single-are light, the

THE MAXIM SYSTEM OF ELECTRIC ILLUMINATION BY INCANDESCENCE.

A most interesting system of lighting by electricity, the invention of Mr. Hiram S. Maxim, is at the present moment being introduced into this country by Mr. J. D. Eckhardt, the financial representative of the United States Electric Lighting Company at New York, the scientific management being entrusted to Mr. Joseph Lockwood, one of the electrical staff of the Weston Electric Light Company, assisted by Mr. Charles W. Farquhar.

The Maxim system, the various apparatus of which we illustrate in the present article, is, like the Siemens, the Brush, and the Lontin, a complete system in itself, having its own special machines or generators, as well as lamps peculiar to itself, and it would be difficult to say whether the Maxim machine or the Maxim lamp is the more characteristic and original feature of the system. Of the two we are inclined to give to the generating apparatus the credit of the greater novelty on account of the arrangement by which the strength of the current is regulated to the work it has to do, this regulating apparatus being upon an altogether new and most ingenious automatic principle.

whole of the current being caused to traverse the coils of the field magnets; but, for incandescence lamps, or for circuits in which the work is at all varied, the current from the machine flows direct into the external circuit, and the magnets are excited by the current from a second machine and exciter, which we illustrate in Figs. 3 and 4, the former being a general perspective view and the latter an end elevation. This apparatus, which, with its regulator, more than anything else, is the characteristic feature of the Maxim system of generating current as his incandescent electric lamp is the distinguishing characteristic of his system of utilising the current, consists of a small dynamo-electric machine, very similar in construction to the larger machine just described, but fitted with but one commutator and a single pair of brushes, and having its armature cylinders wound with a single set of coils; in all other respects, except in size, the exciting machine is similar in principle and general construction to the lighting machine.

The method by which the current from the machine, and therefore the intensity of the magnetic field of the large machine, is adapted to the work on the lighting circuit, is most interesting and highly ingenious. On referring to Fig. 3 it will be seen that the collecting "brushes," which consist of a bundle of fine copper springs or plates, are mounted upon a rocking frame, which is capable of being rotated through a certain angular distance upon the armature spindle by means of a lever, which is geared into by a bevel pinion on a vertical shaft shown on the right of the figure, and this shaft is actuated by a horizontal shaft through the intervention of a pair of bevel pinions. At the upper end of the horizontal shaft is a sprocket gearing into two others, which are mechanically coupled to two ratchet wheels, shown in Fig. 3, but more clearly in the elevation, Fig. 4, which forms the framework being cut away to show the position of an oscillating pawl between the two wheels, by which a reciprocating motion is communicated by means of a rocking lever worked by a connecting rod and crank, clearly shown in Fig. 4. Above this ratchet gearing is a small table carried on four pillars, and to the top of this is attached two electro-magnets, the coils of one of which are considerably higher resistance than those of the other, but it is with the coils of higher resistance that we have to do at present. Above the upper pole of this magnet is a soft iron armature, mounted on a lever, which, by means of an adjustable tension spring shown on the left of the figure, can be balanced, not only against the weight of the lever, to which its opposite end is attached, but also against any required magnetic attraction of the electro-magnet. The mechanical action of the apparatus is as follows: during the working of the machine a reciprocating motion is, by means of a small crank and connecting rod, communicated to the pawl, and is thus carried from position to which the upper lever is adjusted, slightly more than a tooth and forwards into one the ratchet wheels without touching either. If, however, the magnetic intensity of the electro-magnet increases, its attractive force is overpowered by the tension of the adjustment spring, the lever rises, and the pawl is lifted so as to gear into the upper ratchet wheel, and the whole train of counter-shafts will be set into motion in one direction, the following strokes moving around the commutator towards the point of a maximum efficiency; the current sent into the low-resistance coils of the large machine will, therefore, be weaker, thus diminishing the intensity of the magnetic field, and therefore of the current induced in the armature revolving within it. If, on the contrary, the magnetic intensity of the electro-magnet of the regulator decreases, the reverse operation will take place, the pawl will engage in the teeth of the lower ratchet wheel, and the brushes will be moved towards the point of maximum efficiency, and the magnetic field of the large machine will, therefore, be intensified. The mechanical details are so proportioned and arranged that the brushes can be moved through a range which is limited on one side by the zero of efficiency, that is to say, the neutral plane of the magnetic field, and on the other by the point at which the maximum current is collected by the brushes, and between those two extremes the efficiency of the machine can be varied by simply corresponding to the motion of the brushes caused by the rotation of ratchet wheels through an angular distance equal to the pitch of their teeth.

In order to make the work on the lighting circuit constant the smaller machine, and therefore the strength of its own current, the regulator for the large magnet is placed in a shunt circuit derived from the lighting circuit of the large machine. This arrangement will be readily understood by reference to the diagram, Fig. 5, in which M represents

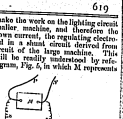

FIG. 5.

the large machine, and R the regulating portion of the smaller machine, P and N are the wires leading from and to the lamp circuit, and x and y are fine wires forming, with the electro-magnet to which they lead, a shunt circuit of comparatively high resistance to the main circuit of the large machine; and, as the current from one terminal of the large through the lamps and the other through the regulating magnet of the smaller machine, it follows that the strength of the current flowing through the latter depends upon the relative resistances of the two circuits; and, as the resistance of the magnet circuit is fixed, while that of the lighting circuit is variable according to the number of lights in action, it further follows that the addition or subtraction of one or more lights from the circuit immediately affects the strength of the derived or magnet circuit, and so adjusts the brushes to collect a sufficient current to give to the magnetic field of the large machine an intensity which is neither more nor less than sufficient for its work.

From the above description the arrangement of circuits is obvious that should a large number of lamps be suddenly cut out of circuit, through the sudden interruption of one of the branch circuits by the accidental rupture of the wire or from any other cause, there would be great danger of the current of full power being diverted by the whole of the current being divided over a smaller number, and, consequently, there would be a great risk in such a case of the machine itself being injured. To protect the system against any either of such results is the object of the second magnet, which is shown at the top of Fig. 3, and which, while being of lower resistance than the regulating magnet, which actuates the pawl, is included in the same circuit. This second or guard magnet is provided with a soft iron armature attached to that of the regulator, but its lever, instead of actuating a pawl, is fitted with a trip or switch, forming, when the current is at its normal strength, a part of the circuit of the helices of the field magnets of the small machine. The moment that the strength of the magnet circuit increases beyond that to which the spring armature is adjusted, the armature of the guard magnet is attracted and the field magnets of the small machine are thereby immediately cut out of the circuit, the exciting current ceases, the intensity of the magnetic field of the large machine is thereby reduced to zero, and the main current is thus momentarily suspended, causing a momentary extinction of the lights but saving them from destruction and the machines from injury.

The lamps employed by Mr. Maxim are in general appearance very similar to those devised by Mr. Swan, of Newcastle,* and like it, consist of a fine filament of prepared carbon in the form of a loop enclosed in a glass globe from which the air has been exhausted, and becoming incandescent under the influence of a current of electricity flowing through it, produces a light of any required power between 20 and 60 candles. Mr. Maxim has given the carbon filaments various forms such as simple loops, Maltese crosses, and other shapes, but the form which appears to have produced the most satisfactory results, and which is adopted at the present time, is a double loop of the form shown in the lamp illustrated in Fig. 6, and which then forms a sort of gridiron grating, having four intermediate vertical filaments. The points which distinguish Mr. Maxim's incandescence lamp from that of Mr. Swan's are the method of preparation of the carbon filaments, and the fact that while Mr. Swan's carbon loops are enclosed in an attenuated residual atmo-

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [April 1, 1884.

ELECTRIC LIGHTING MEMORANDA.

The Englishmen of the Metropolitan Brush Company offer for sale by private contract the complete stock-in-trade and plant of the defunct concern; and their advertisement of the fact is couched in language which unintentionally supplies the bitterest comment upon the position of Brush lighting in London, and indeed in England. Here is a store of dynamos, of recent manufacture and in good order, Brush and Lane-Fox lamps, steam and gas engines, miles of cable, instruments, &c., "all available for immediate use, and ample to provide every requisite for fitting up a number of considerable installations;" and to be sold at a reduction on cost. So this is the end of all the cramp-ring of the Metropolitan Brush Company, who a year ago vainly aimed at dividing London as a spoil. How many times has the world been assured, through the medium of complaisant daily newspapers, that nothing, now or to come, could supersede the Brush system! Alas! for those who trusted in these professions; their ideal has fallen, not through the rumour of the enemies of the new faith, but because of its own congenital rottenness. Reading this advertisement it might almost be thought a dream that a few months ago the simple permission to buy Brush machines for use in the Metropolitan area alone cost somewhere about a quarter or a million of money. A little while, and the debt and costs of the valid portion of the discredited property will be satisfied to the auctioneer's hammer; and the chief popular record of the brief and troubled existence of the Metropolitan Brush Company will be a number of entries on the wrong side of some hundreds of pass-books.

The South-Eastern Brush Electric Light Company have held an extraordinary meeting, against the wish of the Directors, at which the resolutions to which a previous general meeting were rescinded, and practically reversed. It appears that when, as usual, the cost of running the Board had intended to make a call of 10s. per share; but the proprietors set to work, and, before the call could be paid, they demanded that the capital of the Company should be reduced by the amount unexpended, in order to prevent any further waste of money. This the Company who are endeavouring to carry out an installation at Colchester under the Act; and which was confessed by the Directors to be now the only practical fruit of this notorious concern. With reference to the Colchester experiment, several suggestive observations were made by one of the liquidators of the Metropolitan Brush Company, and by the Chairman of the Great Western Brush Company. The former said that it at present impossible to make electric lighting pay in any district; and the latter observed that, if the Company were to put £10,000 into an installation in a provincial town, they should "expect to lose from £2000 to £3000 a year upon it." Against this, of course, the South-Eastern Directors contended that, on the £10,000 to be spent at Colchester in supplying 2200 lamps, there would be a profit of 12½ per cent. Time will show.

The Gilleder Company have succeeded in completing their reorganisation upon a complete basis in respect of capital, upwards of £50,000 having been given up by promoters and founders, and the unnecessary leaving hence streak off. The Company require money, in order to carry on their business at the Crystal Palace and elsewhere; and this is to be raised by the issue of debentures to the value of £12,000, of which the Directors will themselves subscribe £4000. The looks more like business, and should go a long way towards guaranteeing the sum that is so urgently required. It remains to be seen, however, whether this rally of "All" hands to the pumps!" will keep the leaky ship afloat until she enters a safe port. It is a long step down from the high ground taken at first by these Electric Lighting Companies, when they thought they were going to conquer the world, to the quiet unpretentious level of working economy on the scale on which a reasonable profit might yet with due care and diligence be realised. The Gilleder people seem determined to take the step; and nobody will grudge them the small trading profit which is all they hope for now.

Distant Force Acc. March 11, 84.

ELECTRIC LIGHTING MEMORANDA.

It is difficult to see any hope for the Faure Electric Accumulator Company, now that M. Philippart, the manipulator of the English and French undertakings, has become insolvent. When last mentioning the melancholy history of this concern, we stated that the English Company had only two Directors, both Frenchmen, and resident in France. Even these have now resigned; and so the English shareholders are left to look to the—the last men for directors—for help. However, being wholly short of recovering their squandered money. M. Philippart declares that the cause of the ruin of the Faure Companies was the refusal of the English Directors, to prosecute the Electrical Power Storage Company, who, he contends, pirated the Faure patents. He alludes in this to the Sellon-Volckmar combination, which, after all, does not appear to be much worse for supplying that was taken from the owners of the older secondary battery. As for claiming anything from their rivals, the Faure Company probably realize the truth of the old proverb about shearing pigs for wool. Electrical storage is in a bad way just now; and we look in vain for the prosperity that, according to M. Philippart, has been taken from his Companies by the so-called "pirates." The English Company have done all that is possible in the circumstances; they have treated M. Philippart's communications as waste paper, and have appointed a Committee of Shareholders to investigate the affairs of the Company. When this Committee have reported, one more extraordinary chapter will be added to the history of joint-stock enterprise in this country.

The Hammond Electric Light Company have held their meeting, prefaced by a lecture delivered by Mr. Robert Hammond, in St. James's Hall, when he told the audience —which was entirely "paper"—one—that electric lighting could be supplied, on as large a scale as gas, at the equivalent of 3s. per thousand cubic feet. Next day, at the meeting of the Company, the speaker had to confess to a considerable deficiency in the working accounts, and to make other admissions, which show clearly enough that it will never be the lot of the Hammond Company to sell electricity at anything like the rate stated by himself a few hours before. The loss on the Brighton working has been £20,797; to which must be added £7,000 for the loss up to date. For carrying on this ruinous business Messrs. Hammond are paid £1000 a year; Mr. Hammond himself getting £1000 a year, of course, his expenses as a travelling lecturer. This gentleman seems to possess the gift of managing shareholders: for they still go on paying solid cash in return for his oratory, and, at the same time, found it necessary to rearrange their capital, by cutting down the nominal value to rearrange from £5 to £1 10s. Of course the Directors want money to carry on their contracts; but hope to raise this by the issue of new shares. Naturally, the subject of Chesterfield was not mentioned at the meeting. That ugly blunder in the management of the Company admitted by the Chairman was "that they had not started with a far larger subscribed capital." Considering the ability of the Board to go through what money they had, this observation is decidedly refreshing.

A great fuss has been made about the electric lighting of a new municipal building in East London; much ill-blood having apparently been generated in the Town Council by the peculiar way in which the whole affair has been managed. Answer: the only apartments where gas is not laid on as well being some rooms of the library, which will probably therefore be shut at dusk at different periods of the year. The 19-horse power gas-engines being employed for driving the dynamos. In reading the account of the new buildings in the *Lewis Mercury*, we were struck by a mention of one room in "the basement" where—the head-for-the-business department, "medical." *Presumably the Council chamber and Committee rooms do not require special lighting; the necessary "fittings" being supplied by the councillors themselves.*

It is announced that the public electric lighting of Godalming is about to be abandoned and the use of gas resumed for the streets. This is the place which was advertised so loudly a year or two ago, by the *Daily Telegraph* and other London newspapers, as the favoured spot where electricity was soon abandoned, and a portable engine introduced; but now the miserable *farce* is to be dropped, as it ought to have been months ago. It is not to be expected that the daily newspapers will take any notice of this anti-climax to their vapourings of the speculation era.

El Terrocarril

SANTIAGO, VIERNES 14 DE MARZO DE 1884

LUZ ELECTRICA.—Como el alumbrado eléctrico sistema Edison, cuya cesion negoció el Gobierno con Mr. Mackenzie, ha despertado ya con justicia resultados en Berlin, Milan y demas capitales europeas, nos parece oportuno dar algunos datos que hemos recojido en diversas publicaciones especiales y por informes particulares. Desde luego anunciaremos en los diarios de Berlin que la Corte, Reparticion de Alemania ha faltado al precioso juicio inventado de la luz eléctrica incandescente, declarando: en Edison como un mero inventor. Esta decision ha sido sin duda mayor impulso á esta clase de alumbrado, no solo en Berlin, sino en Paris y Londres. Ahora Mr. Edison ha comunicado un nuevo sistema de iluminacion que disminuye considerablemente el costo de la luz eléctrica. En Santiago, donde se ha implantado el antiguo sistema, los conductores cuestan mas de cinco pesos por cada luz, con el nuevo sistema no importa mas de un peso cuarenta centavos, lo que hace con el negocio en mas que lucrativo para los empresarios. Por el sistema antiguo un caballo de fuerza equivalia á 1125 velas; por el nuevo llega á 1450, esto es: beneficio de 25 por ciento, siendo el mismo el gasto del motor. Ademas, por un ingeniosa invencion en el arreglo y funcionamiento de la maquinaria, se obtiene una economia mensual de un 50 por ciento sobre el empleado. Y todavia, las maquinas que hasta ahora valen 90 centavos, se obtendrán á 40. Todas estas economias y ventajas seguramente, mas la estabilidad del alumbrado bajo el sistema Edison que, segun el mismo inventor, presenta la fal petición de los ensayos para entrar en el dia la aplicacion. En Nueva York, la primera estacion central es por el sistema antiguo, y cuesta en conductores, cana, cajabocks, empalmes, etc., un millon de pesos oro, alimentando 12,000 focos. Asi, los accionistas han recibido un dividendo de 6 p. Con el nuevo sistema, un gasto se reduciria á 300,000 pesos; de manera que la utilidad de la empresa va á ser inmensamente. En la estacion habia mas maquinas eléctricas, y mientras en Inglaterra se instalaban otras mas, una de 60,000 focos y la otra de 90,000 en la parte mas central de aquella ciudad. Existen actualmente en Estados Unidos 10 establecimientos centrales, y hai un contrato para establecer dos en cada semana durante el presente año; y en cinco de los estaciones existentes se han aumentado 5,000 focos cada una. Mañana, el decreto en la solicitud presentada por don Carlos Bellet, representante de don Tomas A. Edison, de los Estados Unidos, concediendo que establezca, para la distribucion de luz eléctrica, el sistema Edison.

LITERATURE.

Lectures on Architecture delivered at the Royal Academy by the late EDWARD M. BARRY, R.A. Edited, with Introductory Memoir, by ALTRED BARRY. London: Longmans, Green, & Co. 1881.

That book-making there latures is divided into three heads: a memoir of 70 pages; a series of lectures and notes extending over many pages; general principles, consisting of 385 pages; and a second series of lectures, treating on the historic architecture of days long past, or as it should be termed archæology from an analytical point of view; these last comprising 250 pages, and thus taking up a considerable portion of the book.

Any memoir of those whose works and doings are familiar to us, is necessarily interesting; but when such an account throws light on the circumstances under which an eminent worker out of high and artistic principles has achieved his results, and explains hitherto obscure difficulties that have surrounded his path, it becomes valuable in proportion as it affords a key to the explanation of matters often incomprehensible from the surface, and frequently misjudged.

Among the principal works of Edward Barry were, the additions to the Westminster Palace, the Cannon-street and Charing Cross Hotels, the Ellesmer Cross, the Opera House at Malta, Covent Garden Opera House, the New Temple Buildings, the rebuilding of Crews Hall, Halifax Town Hall, and the Birmingham Institute; his bitter experience in connection with the Royal Exchange Competition, resulted in the 2nd prize being awarded to a Frenchman, and his own design was placed 3rd. Again, his design for the Law Courts was selected in lieu of his own, and the first premium awarded to Mr. Street, who, after the Government had abandoned its intention of carrying out anything further. These prizes were awarded before the Government remembered him in any way. These with other troubles told on a constitution not robust, wore him out, and shortened his existence; he died in January, 1880; and thus passed away a man that gained the highest distinction in competition for architectural employment, as one of the most important public buildings in England. The lectures on architecture proper, that is of the first series before mentioned, are admirable; they show the results of deep thought, close examination, both from an artistic and from a fitting utilitarian point of view, ensuring a right and good judgment. General principles are laid down with breadth and vigour while the "striving as" so frequently translated in every branch of the art, and aided by suggestions in every direction, show the tendencies of a practical enthusiast having "a mind to work" with the whole problem before him. Technical details, artistic improvement, details of practice, progress, retrogressions, and the smoke difficulty are all fully dealt with.

It could be of little use to quote any passages from these lectures: they should be read as a whole by every professional architect and student; and it would be well if even the whole profession were not up to the principles explained. Apart from that, the perusal of these lectures at an interesting moment cannot but aid in producing a greater appreciation of true architectural merit and an intolerance of taste. Some of the phrases of the lecturer indicate his ideas of the habits between architects and the general public as well as with the critics. He says: "Architecture is an art which does not work in seclusion for the benefit of the few, but appeals openly to the many, and I believe is valued by the few who are qualified by study and knowledge to speak authoritatively on its principles, because the broader characteristics must always be those that will interest the intelligent observer. Those also who to see properly will ever require education, and the power of criticism is not an instinct, although the power of grumbling may be so. Knowledge, then, is required in the critic as well as in the artist, and where it abounds, a genuine criticism is of the highest value. It professes to aid the younger aspirants the way of progress, and satisfactory conclusion that accompanies true knowledge."

Also: "I am convinced that there is no reform of more pressing importance in our day than the improvement of the houses of the million; and this is a question in the solution of which architecture should have her share. The living of the many should be as much under the control of the architect as the worship of the few."

Lectures on Architecture delivered at the Royal Academy by the late EDWARD M. BARRY, R.A. Edited, with Introductory Memoir, by ALFRED BARRY. London: Longmans, Green, and Co. 1881.

That book contains three lectures is divided into three heads: a memoir of 70 pages; a series of lectures and notes extending over many pages; general principles, consisting of 385 pages; and a second series of lectures, treating on the historic architecture of days long past, or as it should be termed archæology from an analytical point of view; these last comprising 250 pages, and thus taking up a considerable portion of the book.

Any memoir of those whose works and doings are familiar to us, is necessarily interesting; but when such an account throws light on the circumstances under which an eminent worker out of high and artistic principles has achieved his results, and explains hitherto obscure difficulties that have surrounded his path, it becomes valuable in proportion as it affords a key to the explanation of matters often incomprehensible from the surface, and frequently misjudged.

Among the principal works of Edward Barry were, the additions to the Westminster Palace, the Cannon-street and Charing Cross Hotels, the Ellesmer Cross, the Opera House at Malta, Covent Garden Opera House, the New Temple Buildings, the rebuilding of Crews Hall, Halifax Town Hall, and the Birmingham Institute; his bitter experience in connection with the Royal Exchange Competition, resulted in the 2nd prize being awarded to a Frenchman, and his own design was placed 3rd. Again, his design for the Law Courts was selected in lieu of his own, and the first premium awarded to Mr. Street, who, after the Government had abandoned its intention of carrying out anything further. These prizes were awarded before the Government remembered him in any way. These with other troubles told on a constitution not robust, wore him out, and shortened his existence; he died in January, 1880; and thus passed away a man that gained the highest distinction in competition for architectural employment, as one of the most important public buildings in England. The lectures on architecture proper, that is of the first series before mentioned, are admirable; they show the results of deep thought, close examination, both from an artistic and from a fitting utilitarian point of view, ensuring a right and good judgment. General principles are laid down with breadth and vigour while the "striving as" so frequently translated in every branch of the art, and aided by suggestions in every direction, show the tendencies of a practical enthusiast having "a mind to work" with the whole problem before him. Technical details, artistic improvement, details of practice, progress, retrogressions, and the smoke difficulty are all fully dealt with.

It could be of little use to quote any passages from these lectures: they should be read as a whole by every professional architect and student; and it would be well if even the whole profession were not up to the principles explained. Apart from that, the perusal of these lectures at an interesting moment cannot but aid in producing a greater appreciation of true architectural merit and an intolerance of taste. Some of the phrases of the lecturer indicate his ideas of the habits between architects and the general public as well as with the critics. He says: "Architecture is an art which does not work in seclusion for the benefit of the few, but appeals openly to the many, and I believe is valued by the few who are qualified by study and knowledge to speak authoritatively on its principles, because the broader characteristics must always be those that will interest the intelligent observer. Those also who to see properly will ever require education, and the power of criticism is not an instinct, although the power of grumbling may be so. Knowledge, then, is required in the critic as well as in the artist, and where it abounds, a genuine criticism is of the highest value. It professes to aid the younger aspirants the way of progress, and satisfactory conclusion that accompanies true knowledge."

Also: "I am convinced that there is no reform of more pressing importance in our day than the improvement of the houses of the million; and this is a question in the solution of which architecture should have her share. The living of the many should be as much under the control of the architect as the worship of the few."

and powerful country will be able to rid herself of the reproach that a majority of her area are unable to house themselves with comfort, or even with decency. Such views are better than those of most professional architects. The first series of lectures is followed by a short, but interesting Lecture X., "On Town Architecture and Modern Improvements," and the concluding one of the series. The utilisation of London squares in the way proposed is not perhaps after the best mode of very desirable in any way, but may aid greatly in leading the way to more unique designs in that direction.

The second series of lectures is interesting to the professional student, and shows the manner in which the European architectures of the past, from the Norman castles down to the palaces and buildings of the Third Renaissance period, should be studied; that is, in accordance with the local and temporal circumstances, and with the objects with which such constructions, with their modes of communication, were adopted; this series also explains the principles of architectural development in the past, and so far may be of assistance to those practically interested in producing that which is suitable, artistic, and useful in the future. The more general heading, however, already been more thoroughly gone over by Ferguson in his well-known and much more complete in this respect. Such omissions and shortcomings, after which in local interest, justify the value of the lectures, which will, probably, form a standard volume in every English architect's library.

Pocket Logarithms and other Tables for Ordinary Calculations. By CHARLES HOARE, Architect and Surveyor. Lewes: Now. 18mo. London: Allen, 1881. [Price 6s.]

This very small volume is designed for the use of those who are to perform ordinary, and more than ordinary calculations with exactitude. Common four-figure logarithms are proved by a series of examples to yield very incorrect results, and this error frequently occur in a very large proportion of cases. The tables are simplified to mostly full defect, and yet keep the calculations short. The author justly states that if it were not for the necessity of using four figures in the numbers of a result, it is also stated by suggestions in every direction, show the tendencies of a practical enthusiast having "a mind to work" with the whole problem before him. Technical details, artistic improvement, details of practice, progress, retrogressions, and the smoke difficulty are all fully dealt with.

It could be of little use to quote any passages from these lectures: they should be read as a whole by every professional architect and student; and it would be well if even the whole profession were not up to the principles explained. Apart from that, the perusal of these lectures at an interesting moment cannot but aid in producing a greater appreciation of true architectural merit and an intolerance of taste. Some of the phrases of the lecturer indicate his ideas of the habits between architects and the general public as well as with the critics. He says: "Architecture is an art which does not work in seclusion for the benefit of the few, but appeals openly to the many, and I believe is valued by the few who are qualified by study and knowledge to speak authoritatively on its principles, because the broader characteristics must always be those that will interest the intelligent observer. Those also who to see properly will ever require education, and the power of criticism is not an instinct, although the power of grumbling may be so. Knowledge, then, is required in the critic as well as in the artist, and where it abounds, a genuine criticism is of the highest value. It professes to aid the younger aspirants the way of progress, and satisfactory conclusion that accompanies true knowledge."

Also: "I am convinced that there is no reform of more pressing importance in our day than the improvement of the houses of the million; and this is a question in the solution of which architecture should have her share. The living of the many should be as much under the control of the architect as the worship of the few."

Templeton's Tuschenbuch for Practische Mechaniker. By ERNST TEMPLETON and JOHN GEORGE BRIGHT. Halle: Winkler.

This book forms a text-book for a class of mechanics not educated up to a high standard, unacquainted with higher mathematics, yet possessing a sound middle-class education, and of that kind, very often, with special reference and particularly for the colour working engineers, foremen and workmen of the ordinary stamp, are not nearly so numerous as those for the upper class, and if well carried out, should have a very large circulation. The one before us, with the name of Templeton's Pocket-Book, bears but little or no resemblance to the original work of this title; it is an engineer's hand or reference book with the usual arrangement of contents, commencing with mathematics, a third part consisting of a mechanical section, a third part containing formulæ, rules, and skeletons for designing; and a fourth treating on technological subjects. The book, although of but small proportions, contains an abundance of useful information in over 600 pages, and more than 400 small sketches distributed throughout the volume, add materially to its value. The entire absence of higher mathematics will no doubt be an important feature for all those for whom the book is specially intended, and a series of tables, including trigonometrical tables and logarithms, render it more than usually comprehensive.

That so large a variety of information cannot be very completely given, and be translated as much as possible, is only natural, and the book will, therefore, be more suited for study than for reference, but the general treatment of the different subjects is so complete that it is commonly found in a so-called pocket-books. The title, "Pocket-book for Practical Mechanics," is somewhat misleading, since a great part of the contents would never enter into the sphere of a practical mechanic's occupation, and is really intended for the designing office; but there is, of course, no reason why mechanics should not be acquainted with the principles of design; experience, however, teaches that generally they are not, and very frequently even more complete than the drawing office have but a limited knowledge of what they should know, and that special and of a very practical mechanic. If it succeeds in spreading the information it contains, it will be doing good service.

THE JASPAR SYSTEM OF ELECTRIC LIGHTING.

The system of electric lighting, devised by M. Jaspar, of Liège, which was illustrated at the Paris International Exhibition of 1878 by the jury, who awarded him a medal, attracted much attention among electricians at the recent Exhibition in the Palais de l'Industrie, on account of the simplicity of the lamp, its efficiency in working, the softness of the light produced, and the ingenuity of the whole system. We have referred several times to the Jaspar lamp in these columns, and have also noticed the special arrangement that M. Jaspar adopted for lighting No. 16 at the Palais de l'Industrie, and also the one he has in the cellars of the Paris Opera. The arrangement consists, it will be remembered, in placing the carbon rods, conducting the light at the bottom of a cylinder with opaque sides, which conceal it from view. The luminous rays escape from the upper and open end of the cylinder, and are thus thrown upwards in large white umbrella-like reflector, which diffuses them, and distributes a general diffused, very soft and pleasant to the eye. We shall find in this arrangement the solution of an idea which we have mainly preconceived M. Jaspar. He is not of course in perfect a convenient and simple a regulator, but goes further, to find the means of more effectually distributing the light, as will be also endeavoured to produce, not only light of useful illuminating power, but of light more entirely distinct, although in popular language they are considered as synonymous. We will first divide our into two parts our notice of the Jaspar system, describing first the regulator, and then the lamp in the manner in which he employs it. The Jaspar lamp belongs to the numerous category of apparatus in which the weight of the positive carbon-holder acts as the motive power of the system, and the object of that is to say, it is not adapted to the divisibility of the volts are, and only one lamp can be placed in an electric circuit. Fig. 1 is a side view of the regulator, from which a part of the outer casing has been removed in order to show the mechanism. Figs. 2, 3, 4, and 5 are respectively two vertical and a lower plan. This lower portion of the regulator is shown in Fig. 1 formed of a hollow cylinder be carbon-holder A formed of a hollow cylinder be A, set on. In the middle, the tube C is

ELECTRICITY

And the Wonderful Development.

The Telegraph from the Building of the First Line to the Present Day.

The Invention of the Telephone and Its Almost Universal Adoption.

The Electric Light and Its Importance as an Artificial Illuminant—The Many Minor Applications of Electricity.

The Recently Rapid Extension of Electrical Apparatus Manufacturing Plants.

History of the Western Electric Company, the Foremost Manufacturers of Electrical Apparatus.

Description of Their New Building and of the Company's Manufactures.

In 1837 Morse invented the electric telegraph, and in 1843 he built the first telegraph line, a short strip line between New York and Washington. At this time the application of electricity were few, and Morse's invention was considered a most remarkable one, as indeed it was. Even after the line between New York and Washington was erected only a single wire, adopted of the most primitive and desired whether it would ever be available for commercial uses, improved apparatus and methods, however, soon made the line an entire success. The growth and success of telegraph lines since the time of Morse's early experiments have been truly marvelous. They have been extended and multiplied until they now form a network of wires over the whole land, which are reached by the electric signal. The Western Union company alone claims over fourteen thousand offices, and the continental lines of the country are connected by nearly two hundred thousand miles of connecting links, thousands of miles in length, forming a great intercommunication system, with the entire globe as its territory, and over which is carried the world's business for the existing twenty-four hours.

When Alexander Graham Bell brought out his telephone, less than a decade ago, the public attitude at the time was prepared for a certain class of the startling developments in the electrical field, were limited, nevertheless, to look upon his invention as an ingenious and wonderful toy simply, and not as the first of a series of inventions that were the parent Bell Telephone company, as it is reported to its stockholders, has increased in a term of 40,000 with which to develop its business, in spite of great difficulty in getting its wires, and, in fact, full-sized, which is the standard in use in all the principal cities of the country, and larger areas are required in the business districts of the large cities.

In 1877 a New York inventor, Mr. Edison, built what is known as the "phonograph," which was a machine for recording the human voice and reproducing it at will. This machine was considered a most wonderful invention, and was exhibited in all the principal cities of the country. Mr. Edison, however, was not satisfied with this invention, and in 1878 he began experiments in the direction of electric lighting, which resulted in the production of the incandescent light, which is now in such general use. Mr. Edison's first lamp was exhibited in Menlo Park, New Jersey, in December, 1879, and was the wonder of the day. Crowds visited the place to see the new light, which was then considered a most wonderful invention, and its brilliancy and steadiness were the subject of universal comment. Mr. Edison has since perfected his lamp, and it is now in general use throughout the country. Its use is rapidly increasing, and it has come to be looked upon as a necessity in many households.

The parts are fifteen inches long and one inch wide, and consist of a strip of boxwood, with a groove in each one framed in the bottom of the frame is rediscovered by the inventor of the telephone.

Each frame contains two hundred annunciators, and the building is arranged in eight stories, and each one contains one frame is required. The entire number of annunciators contained in the building would give of these.

Each frame contains at each end a spring-jack, to which are attached the cables, as shown in the illustration, so that each frame is connected with the electric current for the non-breaking of the circuit. The front of each frame also contains the annunciator drops, the light and spacing department is mainly devoted to the manufacture of the Gray annunciator drops, which are the latest and most improved. The cutting, punching, testing, and arranging machines and screw-making machinery are also in the establishment, which is now in full operation, and is turning out a large number of drops daily.

The end of the building is devoted to the wood-working department, in the basement of which is the boiler and engine room, with the necessary machinery for the company by Messrs. Fuller & Warren, of Stamford, Conn., and is of the latest and most approved pattern. The engine is a splendid piece of work, and is a model of neatness and finish.

The machine-shop contains the second and third floors of the building, and is filled with the latest and most approved machines, such as lathes, drills, presses, milling machines, and machinery, in which are to be found all the tools necessary for the fitting up of the work of the establishment of the kind in the world.

The basement is devoted to the manufacture of work in which they are engaged in the manufacture of, and which has been with the exception of the cabinet work, which is done in the city of Cicero. The main facilities in the way of tools for this work are in the basement, and it is here that the heavy work is done. Electric motors are used for driving the machinery in this department, and the work of a large standard of the cabinets, which are made in the city of Cicero.

The first floor of the building is entirely occupied by the offices of the various departments of the business. The main office, adjoining the private office of the president, is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The second floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The third floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The fourth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The fifth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The sixth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The seventh floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The eighth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The ninth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The tenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The eleventh floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twelfth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The thirteenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The fourteenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The fifteenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The sixteenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The seventeenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The eighteenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The nineteenth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twentieth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-first floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-second floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-third floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-fourth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-fifth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-sixth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-seventh floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-eighth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The twenty-ninth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The thirtieth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The thirty-first floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The thirty-second floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The thirty-third floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The thirty-fourth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

The thirty-fifth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The forty-ninth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.

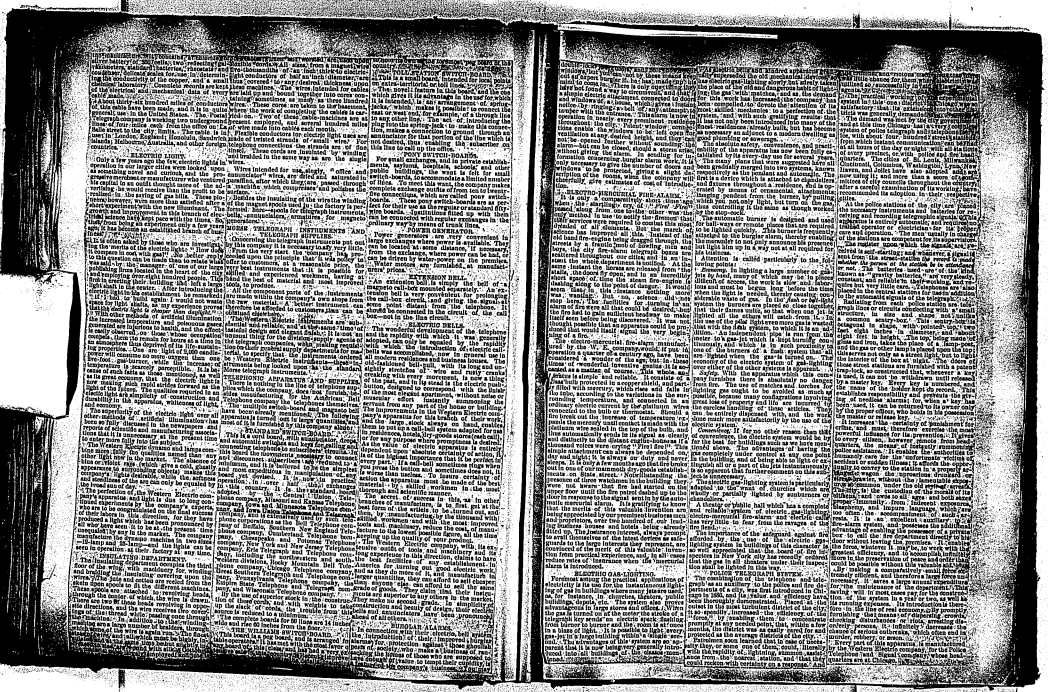
The fiftieth floor of the building is entirely occupied by the offices of the shipping department, which is a model of neatness and convenience, and is admirably adapted to the purposes for which it is used. The offices of the various departments are all conveniently arranged, and are provided with the latest and most approved appliances for the transaction of business.



ELECTRO-MEDICAL APPARATUS.

The company manufactures quite a variety of electro-medical apparatus, and in connection with this section with the other manufactures. Some of their medical batteries are in high repute among physicians, notably the Mendel galvanic battery, which is conceded to be the very best galvanic battery made. The company has taken pains to consult the taste of the purchaser in making these instruments to order; and every battery is carefully tested before leaving the shop. Full directions are furnished with every instrument sold.

The company has been a seriously illustrated catalogue of this kind of material, in which are shown and priced all kinds of batteries, their appurtenances, and electrodes. This catalogue the company sends free on application.

AMERICAN DISTRICT TELEGRAPH APPARATUS.

A few years ago the most promising field for the social and business usefulness of electricity in cities and towns was the district telegraph. The apparatus for calling messenger, doctor, police, or fire-engine, and the wires for transmitting the call, or the alarm of fire, brought well before the public what its utility was even when confined to the mere extended use of the telephone.

The district telegraph has its peculiar adaptations, and it is well that it is so; that is, that the field is small, and that it is coming to be perceived more and more, that the telephone and district telegraph systems are not conflicting in their services, where they render the community, but that they supplement each other.

The Gray district telegraph system, which has so far been made for district telegraph purposes is the Field, A. Firman, eleven-call box with answer-back signal.

One and four-call boxes are considerably used, but the eleven-call box is preferred, as it is adapted to a line with a large number of calls (the language resulting from their use is much more extended), and it is generally found to be advisable to equip a system with the more costly but more flexible instrument.

The advantage of the answer-back signal, by means of which a customer is notified that his call is received and will have attention, is of reality and

The apparatus required for a district telegraph system is not complicated or expensive. The one essential in this apparatus, as in all electrical apparatus, is that it shall be perfectly constructed and thoroughly reliable. Those are the qualities of the instruments made by the Western Electric Company, and which have so far in business are well known, and which have secured to it the pre-eminence in this field.

MULTIPLEX TELEGRAPH APPARATUS.

In the general office of the Western Union Telegraph Company, in New York is a case containing the multiplex telegraph instruments of the immediately next.

They appear clumsy and rude even to the casual observer, but it is only when a visit in the operating-room has shown the beauty and delicacy of the mechanism that one is able to appreciate the vast progress that has been made in the art of telegraphy since its early days. Operations no longer require the register to write out their messages in dots and dashes, but take them from the tape by sound, thereby avoiding the risk of the accident, and accommodating means transmit and receive messages at a speed which the quickest writer of several operators can not emulate.

The Quadruplex and Duplex instruments also are marvels both in their construction and in what they accomplish. By the quadruplex two messages can be sent each way over the same wire, making four messages which are simultaneously transmitted over one wire.

The duplex system is accomplished by the Gray harmonic system, by which two messages are simultaneously transmitted over one wire.

All this improvement over the first device has not accomplished without great expense of time and money, and much of it that properly in the art are marked by many a dial, papers, manual rolls on the shelves of factory storeroom and inventor's laboratory.

Volumnious as are the records of the patent office of the United States, the entries of this great body of work, which has been carried on and noted, be fully seconded by the skillful and faithful carrying out of his designs in the construction of instruments.

Among the latest instruments in use for translating telegraphic signals is the stock of the Western Electric Company, which is in use in the stock exchanges in New York, Chicago, Boston, and Philadelphia, the Gray harmonic, the Miller, and the Edison, with Pender

THE ELECTRIC PEN

of Edison's invention is manufactured by the Western Electric Co., and very largely in demand by those who appreciate the advantages of the duplicating process.

APPARATUS FOR ELECTRICAL MEASUREMENTS.

The practical electrician needs to measure the insulation resistance of circuits, strength of current, internal resistance and electro-motive force of batteries, and to test out the different forms of apparatus and circuits. In telegraph work, and in telephone work, being a new thing, there are new problems connected with it which require to be solved, and the solution of which will, in time, save immense sums of money, which would otherwise be unwisely expended.

The following list of electrical measurement apparatus manufactured by the company (Western Electric Co.) and very largely in demand by those who appreciate the advantages of the duplicating process.

The practical electrician needs to measure the insulation resistance of circuits, strength of current, internal resistance and electro-motive force of batteries, and to test out the different forms of apparatus and circuits. In telegraph work, and in telephone work, being a new thing, there are new problems connected with it which require to be solved, and the solution of which will, in time, save immense sums of money, which would otherwise be unwisely expended.

The following list of electrical measurement apparatus manufactured by the company (Western Electric Co.) and very largely in demand by those who appreciate the advantages of the duplicating process.

The Wheatstone bridge and rheostat is modified after the English pattern or Silvertown standard, and is made by the company with the greatest care, and compares with the original standards in use at the great utility.

The Bradley rheostat and galvanometer, made under the patents of Dr. L. Bradley, has for many years met with great favor, large numbers of which are in use, complete with entire confidence in the great utility.

The Silvertown galvanometer is a new pattern, is neat and compact, and meets with favor.

GENERAL SUPPLIES.

In connection with the manufacturing carried on by the Western Electric Company, they have found it advisable to carry a large stock of general supplies, which are found to be called for by their customers. Thus, a purchaser for a telegraph line may require wire, and will take certain insulators and batteries which he requires, and will look to the Western Electric Company for wire, which has been for constructing the line.

This stock is true of all branches of their trade, so that, besides the large variety of goods included in the regular catalogue, the extensive facilities to which they have become the distributing dealers for the supply of telegraph companies, has led to the adding of many articles which have secured the confidence of purchasers, many of which are not found in the catalogue, and which are only to be had of them.

The stock of these goods, in the line of telegraph supplies, from a pole-step to what is required for the equipment of a complete telegraph system, that this company is not prepared to sell them, in format at the lowest cash prices.

The warehouses at Chicago, New York, and Boston are always full, in anticipation of this class of goods, ready to be shipped out without delay on mail or telegraphic orders.

ELECTRICAL REVIEW

April 7, 1883

The Electric Light Companies.

In the following résumé of the market for electric light shares, the figures given are of the sales that have been made during each week; but higher prices may have been obtained at private sales.

The Edison Electric Light Company, the parent company and pioneer in the field, was originally organized with a capital of $600,000. This was increased to $800,000, and then to $1,200,000. The company owns about 61 per cent. of the stock of the Edison Illuminating Company, which was organized to use the Edison invention in this city, and of the stock of the Edison Company for Isolated Lighting. The value of these holdings is taken into consideration in estimating the value of the shares of the parent company. When its capital was $800,000, its $100 shares sold as high as $2,700. These shares sold at that price. The purchaser of those shares is reported to have sold them at private sale on this same day for $3,000 a share. This original seller paid $2,000 a share. His investment was $1,600, and the second seller made $2,000. All of these transactions, it is said, took place in one day. One of the first transactions in this stock was the sale of five shares for $1,000, or $200 a share. On the day after this sale, the purchaser sold two of the shares for $500 a share, thus recovering the amount of his purchase money for the lot. He afterward sold the three remaining shares for about $8,000, which was his profit on the venture. At times the price jumped up $100 a share in an hour. The son of the president of one of the largest corporations in the country sold 20 shares that cost him $2,000—that is to say, $100 a share—for $20,000, or $1,175 a share. The purchaser sold the stock shortly afterward for $1,870 a share. The stock is now selling at the lowest figure it has touched since it came upon the market recently, $700 a share. A sale was made at that figure not long ago. The price has twice been affected by the increase of the company's capital, as the increase in capital has been offered to the stockholders at par. At the present market value of the shares of the Edison Illuminating and of the Edison Isolated companies, it is estimated that the stock of the parent company is worth about $100 a share, merely as representing the interest of each share in the aggregate market value of the stocks held by the company.

The capital of the Edison Illuminating Company is $1,000,000, and the par value of its shares is $100. Fifty-one per cent. of its stock was given to the parent company for the Edison patents, which it is entitled to use exclusively in New York City. The company proposes to light the city by electricity. Its first district is bounded by Spruce street, Park row and Broadway, and the East River. It has equipped an engine-house in Pearl street, and laid wires and put in fixtures extensively through this district, but has not yet succeeded in furnishing any light to speak of, though it has about 6,000 lamps, which have been lighted at times. The stock of this company has sold as high as $125 a share, and as low as $80. The former price is the one which was reached before the company had put much of its plant, and the latter a few months ago. The last sale is reported to have been at $99 a share, and it is now offered at $90, $40 a share being bid for it.

The Edison Company for Isolated Lighting was organized with a capital of $500,000, which was subsequently increased to $1,000,000. The par value of the shares is $100. The object of the company is to furnish light by the Edison system, and patents to single buildings or establishments. Fifty-one per cent. of its stock is owned by the parent company, having been issued to it for the patents and privileges. When the capital of the company was $500,000, its stock first sold up to $315 a share, and then as low as $175 a share. The stock now brings $150 per share. It is offered at $155, and $150 is bid. The price at present, however, depends to an extent upon the number of shares offered or bid for. This is the only Edison company that has paid a dividend. One of one per cent. and the operations of the last year are recently been declared. Though the parent company has never paid a dividend, large profits have accrued to its stockholders by two awards of new stock at par at times when the premium was very great.

The Edison Electric Light Company of Europe was organized about two years ago, simultaneously with the other offshoots of the original company. Its capital is $2,000,000, and the par value of its shares $100. It has a monopoly of the Edison system in Europe. Its stock sold soon after it came on the market at $165 a share, and has declined to $40. The present quotation is $40 bid, $45 asked.

The capital of the United States Electric Lighting Company is $1,000,000. Its shares, of the par value of $100 each, sold about three years ago at $300 per share. During extreme depression in this class of stocks about six or seven months ago its shares sold at $68.50 a share. The last reported sale was at $125, and at present $110 is bid and $120 is asked. The company has just declared a first dividend. It is five per cent. in cash, but whether it is to be considered as an annual, a semi-annual or a quarterly dividend cannot be learned.

The patents of the United States Company are used extensively in this city by the United States Illuminating Company, which has a capital of $1,000,000, only one-half of which has been issued. The transactions in its stock have been large. The last was at $188 per share.

The Brush Electric Company of Cleveland sustains practically the same relation as the Edison to several minor companies. It has a capital of $2,000,000 in 40,000 shares. The stock sold recently at $110, and it is said that it can be bought at that price now. The present bid price is $100. It has never sold below its par value. The company has paid quarterly dividends of two per cent. for three years.

The Brush Illuminating Company of New York owns most of the stock of the Brush Electric Light Company of New England, which uses the Brush system throughout the Eastern States. This stock is not much in demand, but is supposed to be worth about $600 or more a share. The company has just declared an extra cash dividend of 20 per cent., making a total for the year of 30 per cent., that it has paid within a year. The report is current that the New York and New England companies contemplate a consolidation.

The Fuller Electric Company manufactures electrical machines. It has a capital of $600,000, of which $400,000 is common stock and $200,000 preferred. The par value of both classes of stock is $100. The company has sold from $53 to $62 a share, and the preferred from $66 to $75 a share. Present nominal quotations are 50@55, for the former, offered at $58, and 67@70 bid and $100 asked for the preferred.

The American Electric Light Company has been distinguished chiefly for the economy of its plant, and from the sums of its officers exchanged a few months ago. The company has a capital of $600,000 in $50 shares. Some of these shares have sold at $35. They are now offered at $4.75.

The Brush-Swan Electric Light Company is the last organized enterprise of this class. It combines all the Brush and Swan patents, and is now electrically promoted by the Brush process in the Swan incandescent lamp. The capital of the company is $500,000, and the par value of its shares is $100. Sales have been made at $180 a share, and it is now quoted at $105, and $150 asked.

For the business, protection of their patents, all of the leading electric light companies formed, some two years ago, the Gramme Electrical Company. The shareholders are the American Electric Company, of New Britain, Conn.; the Brush Electric Company, the Edison Electric Lighting Company, the Fuller Electrical Company, the Maxim Electric Lighting Company, the United States Electric Lighting Company, and the Weston Electric Light Company. The stock has no marketable value.

While the prices that now prevail for the shares of most of the electric light companies are the lowest that have ruled, it will be observed that there has been a considerable recovery in the case of those companies which have demonstrated that selling to make returns upon the money invested in them. Those, however, are few in number.

The Electric Light in the Magasins du Louvre, Paris.

Our esteemed contemporary, *Engineering*, in speaking of a previous article published on this above installation, says that we explained that this installation, very carefully arranged in a practical point of view, is directed with great care, and that a very detailed account is kept of the expenditure involved. The figures we shall now give, and which we owe to the kindness of M. Honoré, are therefore absolutely exact; they are deduced from a careful examination of the official accounts, and refer to the year 1882, during which the electric lighting of the Louvre was conducted under normal conditions, without any change or interruption.

As we stated in our previous article, the lighting of the Louvre is effected by five Gramme machines with independent exciters; each of these supply eight circuits of three Jablochkoff candles, or 120 in all. There are two Méritens machines, each of five circuits, feeding thirty candles in all, or a total of 150; there are, besides, four other dynamos, each working as an arc lamp, and one Edison machine, type Z, supplying sixty incandescence lamps.

The expenses relative to this installation have been separated from the general accounts, and divide themselves into three distinct classes, as follows:

1. Those of first cost.
2. The running cost of the lamps.
3. The cost of maintenance and working.

In any ordinary installation the first costs are generally easy to arrive at; the second are usually calculated more or less approximately; as regards the third, it is rarely that running and maintenance charges are recorded with accuracy; these, however, are the most important of all.

During 1882 the Jablochkoff candles, many of which it will be remembered were burning the day as well as at night, gave a total of 204,672 hours; the four arc lamps furnished each 730 hours, or a total of 2,920 hours; as they are each equivalent to five candles per circuit, as far as mechanical work is concerned, their proportional part corresponds to 5,032 × 5 = 14,600 hours. The sixty Edison lamps more recently placed, furnished during the months of November and December last, 720,200 hours of light, but each of them absorbed only 0.3 of the power taken by a candle, so that the proportion of power absorbed was 0.3 × 20,203 = 6,061 hours. We have thus a total of 204,672 light hours of equal intensity. The foregoing is the data from which the distribution of expenses (management, fuel, sinking fund, &c.) has been arrived at for each of the different systems.

Of the 204,672 hours of lighting supplied by the Jablochkoff candles corresponded a total of 2,108,340 candles consumed; hence the average duration of each candle was about 1½ hours. While part of the expenditure works out at a trifling price as which the candles are used in the Magasins du Louvre, it will be found that the cost of working (1.10) per hour; the cost of working and maintenance corresponds precisely with the same figure; as to the allowance for sinking fund, calculated at 10 per cent. for interest and amortization of all the capital invested, in the installation—for boilers, steam power, material of all kinds, conductors, lamp brackets, &c.—it corresponds to a total of 0.145 francs (1.20d.).

The whole of the expenses, therefore amount to 0.393 francs (3.70d.) per hour, divided as follows:

	FRANCS.
Candles	0.134
Motive power and main'ce.	0.124
Sinking fund and interest..	0.140
Total	0.393 (3.70d.)

The cost of the arc lamps is made up as follows:

	FRANCS.
1. Of the cartons consumed, which, divided by the 2,920 hours of lighting, cost per hour more	0.221
2. Of the maintenance as before	0.620
3. Of amortization charges	1.001
Total	1.843 (17.68d.)

Lastly, the account for the Edison lamps stands as follows, allowing a service of 800 hours per lamp:

	FRANCS.
First cost 7.5 francs (6s.)	0.0094
Maintenance	0.0248
Amortization	0.0191
Total	0.0533 (.51d.)

It should be observed here that the general expenses connected with the production of motive power are, in the original accounts, grouped together, and that the distribution made has been arranged proportionally among the different systems, whilst the expenses special to each system, are in all cases kept separate.

An observation should here be made on the hourly consumption of the Jablochoff candles. Until the year 1882 the lighting of the candles was carried out in multiple chandeliers at the Magasins du Louvre, and with hand commutators manipulated by an attendant, when it was necessary to substitute a new candle for one that was burning out. In consequence of this, in order to avoid accidents, it was necessary to be always a little in advance, and consequently to sacrifice a certain amount of the candle which was not yet burnt. Moreover, when the candles in the first chandeliers of a circuit were lighted simultaneously, it was necessary to regulate the change either by the candle which had burnt the quickest, or by the shortest one of the group. From this it followed that none of the candles were entirely consumed, and a considerable waste was entailed. The suppression of this loss was a problem which long occupied the attention of those using the Jablochkoff candle, and many special devices have been achieved for the automatic lighting of the candles. Unfortunately, all these arrangements, more or less complicated, have failed to answer in practice, although great ingenuity has been exercised on the subject. At the Magasins du Louvre, the practical management of the electric lighting is placed, under the superior direction of M. Honoré, in the hands of a chief electrician, M. Clariot, for a long time in the employment of the Jablochkoff Company. This gentleman has carried out an idea at once very original and very practical, by which, at an increased cost of something less than one centime per candle, the relighting can be effected automatically and without any failure, and to secure an economy of twenty per cent. on the consumption of the candles, by avoiding the constant loss of unburnt ends of candles. This arrangement of M. Clariot, the description of which we mean reserving for the present, thus prevents large losses without any delicate mechanism, and with a certainty that has never failed. Thus manifested, the cost of the Jablochkoff candle per hour is

	FRANCS.
Candle	.101
Maintenance	.124
Sinking fund	.146
	.373

In order to afford a means of calculating in what proportion the various systems of electric lighting which have replaced gas are more economical than the latter, we may add that the Magasins du Louvre pay at present for gas .30 franc per cubic meter (6s. 8d. per 1000 feet), which is equivalent to a cost of .054 franc per burner of 180 liters per hour (6 cubic feet). The maintenance would cause to .003 franc, and the amortization of the installation, calculated on the same basis as for electricity, to .014, or a total of .072 franc (1.60d.) per hour and per burner of 6 feet of gas. The total cost of gas lighting is thus raised to about 8c. 6d. per 1000 cubic feet. We have already seen in the previous article that there has been established at the Louvre one Edison lamp for one gas burner of 6 feet, and one Jablochkoff candle for about ten such burners, while more lately five candles in one circuit of a De Méritens machine have replaced a Bengrot arc lamp.*

Consequently, if we compare the cost of lighting by each system, with 1c. light furnished by one cubic meter (28.3 feet) of gas, we shall have the following values:

	FRANCS.
Cost of gas per meter	.300
Edison lamps .0533	.266
.186	
Jablochkoff candles without the	
Clariot device .393	.918

Or calling the cost of gas 1, that of the Edison and Jablochkoff lights are .76 and .332 respectively. By comparing M. Clariot's arrangement for relighting the candles, the cost is reduced to .307, and that for the arc lamp to $\frac{1.819}{1.650}$ = .195; these compared with gas taken as unity, stand at .22 and .495 respectively. The cost of lighting the gas at the burners, and that of the electric lights, is not included in the comparison, which supposes that in either case this work is done by the staff of firemen retained permanently by the establishment. If, however, this item was estimated, it would increase the cost of the gas lighting and of the Jablochkoff candles without the Clariot apparatus, and would not affect the other systems.

We may now examine a little more closely the cost of lighting by the Jablochkoff system, which has been most elaborated in this installation. We see that is the cost per hour (.373) franc the cost of the candle itself is only a small item, and is one that will be still further reduced, to a certain extent, by further developments to be made in manufacture. Consumption and maintenance correspond to .124 franc hourly. But little saving can be looked for in this direction, because the steam engines employed at the Louvre are of a very economical type, and consume a minimum quantity of coal per hour. With extravagant engines, the element of cost would run up very rapidly, which shows that the selection of a good motor is of primary importance in obtaining economical conditions in electric lighting. The sinking fund for plant and material forms a heavy item. The cost of electric machines and conductors is a large proportion of the whole cost, and which it may be fairly hoped will in time be reduced. The principal attention of many electrical engineers is directed now, and towards new inventions, but to cheap production, and advance is made in two different ways by improvement in construction, and by making larger and more powerful machines. Thus, of the three elements of cost,

* Photometrically, five Jablochkoff candles approximate very closely to one Bengrot lamp; actually, however, the luminous value is higher, on account of the greater facilities for distributing the light.

the first will be gradually reduced to a small extent by improvements in the production of carbons; the second must remain nearly constant, as but little economy can be made by motive power. Thanks to the employment of more powerful electric generators the latter source of expense may be considerably diminished, since the current can be produced more cheaply on a large scale, and the first cost of installation can be reduced.

But little remains to be added to complete this description of the electric installation at the Magasins du Louvre. Reference has been made to one of the generators employed for the transmission of power to a distance. The current produced by this machine flows through a circuit of insulated wire which crosses the Rue St. Honoré and goes to one of the smaller buildings belonging to the establishment. Here the wires are connected to a second Gramme machine, which drives an air pump by means of which the small balloons that are given away are inflated.

At one time this work was done by two men driving a hand-pump, who were occupied the whole day. The transmitting and receiving Gramme machines do this work in six hours, during which time they fill from 800 to 1,000 balloons. There is in addition a second and more important installation, but not yet completed, so that its description must be deferred for the present; this is in a large building erected near the Change de Paris, where, amongst other things, furniture covered with stuffs, such as sofas, chairs, &c., are made; this workshop contains a number of sewing-machines which will be driven by the current. When the installation is complete we shall describe it in detail.

Engineering, March 17, 1882.

ELECTRICITY.

C. Holden, Mass., will extend its fire-alarm telegraph to Brookside.

All the necessary apparatus has been fixed up in the Parliament House, Quebec, for lighting the Council Chamber with the electric light. It is intended to make a trial in a few days.

The Cincinnati & Hamilton Telegraph Company has completed a line to Hamilton in that city, has erected a wire to Hamilton, Ohio, and will open communication between the two places for business, both for the purpose of transmission of various and special messages.

Electrician Sawyer has discovered a cement which he claims will not be affected by change of temperature, and by which telegraph insulators will be cemented to the pin, and which will not adhere to the glass and metal so closely that it will be impossible to remove them. It will not melt under 500 degrees Fahrenheit. Sawyer thinks it cannot be analyzed, and consequently will not patent it.

Mr. Edison determined about two weeks ago to have the entire plan for electric lighting conducted by experts, owing to unfavorable criticisms that have been made. Accordingly Prof. Barker, of the University of Pennsylvania, and President of the American Association for Advancement of Science, Prof. Rowland and other eminent scientific have had free access to the laboratory and machine shop. The report will be made in a few days. It is understood that it will be favorable. Meanwhile Mr. Edison has sold his patent on electro-autograph to the Western Union Telegraph Company for $500,000.

Pierre Valvour, of Lockport, N. Y., has invented a telephone cable. A metallic, elastic, steel vessel, about thirty feet long, contains the conductors and wire. This vessel about 100 feet in the wake of the vessel. When cables have been accomplished, an automatic connection is made with the cable on board the vessel. By this, as the vessel goes on, finds its way to the bed of the ocean. At the point where the sinker is attached the wire is much heavier for a distance of 2000 feet. This at every 200 miles, this shell, which is full of electrical apparatus, is attached. It releases a sinker, thus bring a telegraph wire on the bed of the ocean. The object of the shell is that the wire shall not be at the mercy of the rolling and pitching of the ship.

COMPARATIVE COST OF GAS AND ELECTRIC LIGHT.

TO THE EDITOR OF THE MANUFACTURER AND BUILDER:

In the April number of your journal, I read an article entitled "Comparative Economy of Gas and Electric Lighting," a subject of such importance and universal interest that I am tempted to ask you for a little fuller information regarding the manner of arriving at some of the figures that appear in your treatment of it.

Taking, for example, your calculations on the cost of lighting the Riverside Mills with Edison's appliances. You estimate the cost of the necessary plant, including a 500 horse power engine, with its machines and boilers, at $15,000. This, you say, means an interest of $1.50 per hour for fighting ("including 8 per cent interest on investment"). I cannot make it mean that way, and would ask you to correct my figures. In the first place, the year, I take 6 per cent for simple interest. But how many of the 8,760 hours in the year is the depreciation by final destruction that the engine is subject to? I should think, from my limited knowledge of such matters, at least fifty per month of 6—and how long will this proportion of it last? In other words, what is the life of this class of machinery? If we reserve 50 years, that would necessitate charging 1 per cent per annum for a sinking fund to replace the loss of $15,000 of investment in 50 years. Then, taking the salary of a competent engineer at $60, I have

6 per cent on $15,000 = $900, simple interest.
1 per cent on 15,000 = 150, sinking fund.
Engineer's wages..... 60

Interest and attendance, $1,100 per annum.

Again, I believe the estimate can be reached, it must be known how many hours a day this engine, with its 1,000 lights, would be started up and run. For all the year round, long hours and short days, I think it would be fair to fix Mr. Edison by his hours a day for 300 working days. This gives 600 hours a year on the machine, useful time of the engine and the rest of the investment in 50 years. Then, taking the salary of a competent engineer at $60, I have

6 per cent on $15,000 = $900, simple interest.
1 per cent on 15,000 = 150, sinking fund.
Engineer's wages..... 60

Interest and attendance, $1,100 per annum.

Again, I believe the estimate can be reached, it must be known how many hours a day this engine, with its 1,000 lights, would be started up and run. For all the year round, long hours and short days, I think it would be fair to fix Mr. Edison by his hours a day for 300 working days. This gives 600 hours a year on the machine, useful time of the engine and the rest of the investment in 50 years. Then, taking the salary of a competent engineer at $60, I have

$900, annual interest on $15,000.
150, annual cost of repairs, etc.
60, fuel.

$1,050, for say 1,000 hours, or $1.05 per hour as above.

In this estimate, which, as above stated, we give purely as a guess, it is stated in the article that no allowance is made for depreciation by use of machinery, and it is evidently meant to include the wages of an engineer for attendance, and also for repairs.

Now, I have already been assured that the additional power and attention required when the lights are turned on is looked after and supplied by those already employed about the mill, without demanding a specially chosen attendant. When the machinery is conducted on as large a scale as here, however, it is to the least very questionable whether special services could be dispensed with, and the expenses of the service would necessarily go to swell the cost of the light.

Taking even this as the basis for the economy of Mr. Edison's lighting system—say 105 candle lights per hour—there would still be a very wide gap between the cost of such a project which has so many warm friends and advocates, and the comparatively cheap cost of gas, which we have seen before the electric light will be able to compete with in any but exceptional purposes. One great advantage of gas-light lies in the simplicity of the arrangements for its distribution, and the facility for measurement and sale, while the machinery of any electric lighting system that aims necessarily to secure the electric current for domestic use, is so very complex if highly refined and delicate, as to call for the employment of the most expert talent to attend to the cost of actual service. At Mr. Edison's laboratory things may work smoothly enough, but Messrs. Brush and Harvey could, going to down their hill gloves every time they went a light.

Taking the above estimate of relative economy of gas and electric light, which we should have no fair figures of several gentlemen who have examined and expressed their opinions of the Edison system, will, we think, be far nearer the truth than those which "Piscean" calls into question. In his estimate of the cost of the electric light he has evidently taken the price of 28 candles (which is the usual duty assumed for a 5 foot burner, and also the average rate of one candle per hour per hour, based on the practice of first-class shops, to be 4 mills, which includes fuel, attendance, repairs, and rent, as follows:

Authority.	Light in One Hour per Candle.	Comparative Cost of Illuminating Gas per M. Feet.
Edison, annual cost.....	1-4	$2.80
Sawyer & Man, "	1-4	2.80
Elv., "	1-5	3.50
Thurston.....	1-3	1.05
Sawyer and Man.....	1-3	1.05
Martin.....	1-2	1.40

Taking the best of these figures, we are safe in saying that if coal gas can be put in the holder at a cost of 85 cents, or less, the economy and simplicity of lighting by gas-light will still continue to give it the preference over the electric light with its costly plant and very delicate appurtenances, even supposing the cost of the plant to the case of the electric system would not exceed that of the other, which is certainly not the case. But the figures we are posted, know full well that illuminating gas can be had, and that at a profit, for even less than 85 cents per 1,000 feet, and the local competition between gas and electricity for some years to come will be eagerly watched by the admirers of the latter.

From the previous statements made, the calculation of cost would be for 1,000 hours of service for 105 home-power engines, or above assumptions of 4 cts. per hour per horse-power:

6 per cent interest on $15,000 per hour.....	9
Fuel.....	2
	$11

This result, we think, will be a much closer approximation to the truth than $1.05.

Successful Electric Lighting.

Of the older electric light companies much has been written and said in our columns during the past year or more. Their success as pursuit, local or general, has been canvassed and been circulated in the daily and weekly press all over the land, and especially when over a local organization had been started. Their system was thoroughly and colefully expounded by them, and sought to be, in an unctious public, only too willing to take any light from a tallow candle to the electric fluid-smelling gas. From a sanitary point of view, nothing has yet been written upon this important subject, that does full justice to the case. Whether we shall continue, so to speak, electricity in furnishing a healthful light, or have a poor illuminating, nauseating, smelling gas consume us, is a question of vital importance to ourselves and our posterity, and one that will sooner or later command the attention of the thinking public, as it deserves. Important beyond comprehension at the present day is this one question, and when public sentiment is well aroused it will be sensibly apparent that the future of all electric lighting is solved without regard to cost. The people have progressed in the latter respect very materially since the first introduction of gas-light, and will take a broader and more liberal view than they did in the beginning, and as a natural consequence more willingly pay a fair price than to-day than ever before. The progress has not been slow, but the public is not posted on the question. The patient work of the inventor's brain has discovered new methods of overcoming difficulties; and the practical energy of many men in properly introducing these various appliances to the public would ultimate in giving it the preference over the electric light with its costly plant and very delicate appurtenances, even supposing the cost of the plant to the case of the electric system would not exceed that of the other, which is certainly not the case. But the figures we are posted, know full well that illuminating gas can be had, and that at a profit, for even less than 85 cents per 1,000 feet, and the local competition between gas and electricity for some years to come will be eagerly watched by the admirers of the latter.

From the previous statements made, the calculation of cost would be for 1,000 hours of service for 105 horse-power engines, or above assumptions of 4 cts. per hour per horse-power:

6 per cent interest on $15,000 per hour.....	9
Fuel.....	2
	$11

This result, we think, will be a much closer approximation to the truth than $1.05.

ELECTRICAL REVIEW.

Successful Electric Lighting.

Of the older electric light companies much has been written and said in our columns during the past year or more. Their success as pursuit, local or general, has been canvassed and been circulated in the daily and weekly press all over the land, and especially when over a local organization had been started. Their system was thoroughly and colefully expounded by them, and sought to be, in an unctious public, only too willing to take any light from a tallow candle to the electric fluid-smelling gas. From a sanitary point of view, nothing has yet been written upon this important subject, that does full justice to the case. Whether we shall continue, so to speak, electricity in furnishing a healthful light, or have a poor illuminating, nauseating, smelling gas consume us, is a question of vital importance to ourselves and our posterity, and one that will sooner or later command the attention of the thinking public, as it deserves. Important beyond comprehension at the present day is this one question, and when public sentiment is well aroused it will be sensibly apparent that the future of all electric lighting is solved without regard to cost. The people have progressed in the latter respect very materially since the first introduction of gas-light, and will take a broader and more liberal view than they did in the beginning, and as a natural consequence more willingly pay a fair price than to-day than ever before. The progress has not been slow, but the public is not posted on the question. The patient work of the inventor's brain has discovered new methods of overcoming difficulties; and the practical energy of many men in properly introducing these various appliances to the public would ultimate in giving it the preference over the electric light with its costly plant and very delicate appurtenances, even supposing the cost of the plant to the case of the electric system would not exceed that of the other, which is certainly not the case. But the figures we are posted, know full well that illuminating gas can be had, and that at a profit, for even less than 85 cents per 1,000 feet, and the local competition between gas and electricity for some years to come will be eagerly watched by the admirers of the latter.

COST OF ELECTRIC LIGHTING AS COMPARED WITH GAS.

An American paper states that the Brush Electric Light Company receives $7,400 per annum for lighting Fourteenth street, New York, from Fourth to Fifth avenue, Fifth avenue, and Broadway to Fifty-seventh street, and the latter street from Fifth avenue to Broadway. In addition, the company, under its contract, also furnishes two lamps, six lights each, in Union and Madison squares respectively. The street lamps have been lighted for several months; those in the squares have been in operation for a shorter period. The illumination is said to be fully satisfactory. The tower lights, however, are effective only upon a small area, and it is also thought that their effect will be still further impaired by the heavy foliage in summer. The total number of gas lamps which it has been possible to extinguish by the substitution of electric lamps is 450. The municipality of New York formerly paid $17.50 per lamp per annum, which is estimated to have been at the rate of about $1 per thousand cubic feet net; but it is stated that that rate was so low that the gas companies did not care about lighting the streets, the gas lights, therefore, cost the city (and probably the producer) $7.50 per annum. The cost, as reduced by the electric light at a cost of $7,400, is a substantial point, however, and under the Brush Company, as in London, more or less money at this time. The advertisement alone, in either city, is worth something, and it is just possible that this company may succeed in making the contract, at all events, on terms as to be very little margin of difference where gas is supplied at $1 per thousand cubic feet. This, however, it should be clearly understood, is much less than the charge made to private consumers of gas in New York.—*London Architect.*

LA LOMBARDIA 30 Giugno 1882 N. 178

La luce elettrica al Teatro della Scala. — La luce elettrica secondo il sistema Edison farà conoscere ricreerà dal nostro egregio amico ingegnere James Shepherd, sarà quella ventura stagione di carnovale applicata all'illuminazione del palcoscenico del Teatro della Scala.

Dopo gli splendidi esperimenti fatti al Ristorante della Scala e al Caffè Biffi, e l'applicazione negli Stabilimenti di Benigno Crespi e del sig. Andrea Ponti, ora tempo che la si adottasse stabilmente anche nella nostra Milano.

ELECTRICITY.

Thereare now 97,000 miles of submarine telegraph cable in use the world over.

The French Atlantic Cable Co. charges fifty cents per word from New York to Great Britain or France.

The Pacific Coast Wire Company connecting Arcata with Eureka, Cal., is still lacking to complete the telegraph circle about the earth.

Altoona's City Council having refused to go to the expense of a telephone for the Mayor, he has connected with the police and will have one erected anyhow.

The electric lights on the City of Berlin has given such general satisfaction that it has been permanently adopted for lighting the saloon, steerage and engine rooms, and will soon be supplied to the other vessels of that line.

H. C. Spaulding and Oliver Harmer, of Topeka, have been trying to arrange with the water-power company in that city to furnish power to run a dynamo for lighting the city by electricity. The proposition is to place lights on high towers at the intersection of principal streets, and they want to run the apparatus with water-power.

An interesting experiment with an electric head-light for sea-going vessels was tried in this city on the evening of the 25th. The air was impregnated with sufficient salt to bring into full relief the beam of light, which was about eight inches in diameter at the reflector, and could be seen for a distance of about a mile. Objects on the other side of the river, the colors in which they were painted and in many instances the letters of their inscriptions. The danger attributed to such lights hereafter has been that the reflection was thrown back into the eyes of the pilot and helmsman, blinding them to all distant objects. But with this present one there is no disadvantage. The reflection is cut off by the smoke-stack, and the only consequence is the fade away in the spar only objects remote from the ship are made plainly visible. As long as the result of dust is more clearly outlined, though some of it is reflected back; in a thick fog it appears to be a bright, white spot. In the Scientific Review, let in the densest fog it will penetrate a distance of 1,000 feet. The light is to be tried on the steamer Scotland at the first favorable weather that lends to the mind of an intensely illuminated fog, and knowing at once the snow would obviate the danger of collision. Such an illuminator would have prevented the recent disaster on the Seine of the collision at sea.

THE ELECTRIC LIGHT,

A BI-MONTHLY JOURNAL.

GEO. R. MORSE, - - PUBLISHER.

THE ELECTRIC LIGHT will be sent to any address free of charge. While especially devoted to the interests of the Fuller Company's system, it will aim to notice the progress of electric lighting in general, and such other of the manifold applications of Electricity as may be of interest to the business public.

Previous issues, containing much interesting information, may be had by applying to the Fuller Electrical Co., No. 44 East 14th St., New York, or Box 512, Rochester, N. Y. Address,

THE ELECTRIC LIGHT.

DIVIDEND NOTICE.

THE FULLER ELECTRICAL COMPANY.

New York, June 31, 1882.

The Board of Trustees of this Company have this day declared a dividend at the rate of 12 per cent. per annum on the preferred capital stock, out of net earnings for the first five months of 1882, payable on Monday, July 2, 1883, at the office of the Company, 44 East 14th St., New York City, to stockholders of record, June 20, 1883.

The transfer books of the Company will be closed on Wednesday, June 30, and will be reopened on the morning of Sunday, July 2, 1883.

H. SEMOUR GRAVY, Treasurer.

EDITORIAL NOTES.

The new semi-incandescent lamp of the Fuller Company is a great success.

"Our lights run uniform and steady." D. W. Powers, Rochester, N. Y., using 45 Fuller lights.

"I am saving twenty-five dollars a day." Wm. Gleason, Rochester, N. Y., using 10 Fuller lights.

"One of my best investments," says Gen. S. McConkey, Toronto, Canada, using Fuller lights in his refreshment parlors.

The people of an Austrian village recently broke all their kerosene lamps, because they caused most of the fires in the village. The electric light will satisfy them.

Besides the electric light, two or three new processes for producing gas cheaply without coal or petroleum are designed to make gas tyrants tremble.

The Fuller Company is now manufacturing the largest dynamos ever made in the United States for standard lighting, in which they are applying their current regulator with the best results.

In our own country, where a factious opposition exists, on the part of many, to everything that savors of privilege, it is a matter of congratulation that inventors and promoters of electric lighting ought to be given to any corporation whatever.

A correspondent of the Rochester Post Express, writing recently on the subject of street lighting, condemned the clear glass globes ordinarily used, as being productive of dark shadows and unpleasant contrasts. He commends the electric light of London and Paris, "where," he says, "the electric light is seen in its perfection." He continues, "As an illustration of all this, one has but to observe the light used by D.W. Powers in front of his building. These are the only lamps in the city that approach the perfection of the London and Paris lamps." We merely add, for the benefit of those not acquainted with Rochester and its far-famed "Powers' Block," that those lamps are furnished by the Fuller Company.

The electric is much richer than the solar light which reaches us, especially in what has been called the chemical and violet rays. What light is omitted from the carbons and bluish, purple from the arc. The combination of the two gives a characteristic tinge of bluish white.

The secret of the Fuller Company's success may be found in addition to its excellent apparatus, long since proven by undeniable testimony, in strict attention to the wants of its patrons, and care in looking after all the minute details of its business. These principles always secure the favor of a discriminating public.

We regret our inability to notice, as we had hoped to, the electric light display at the Chicago Exposition of Railway Appliances. The lights of all companies aggregated several hundred and lighted the immense structure and grounds as they could not have been illuminated under any other system. The Exhibition closed so suddenly, it was not practicable to have the tests of the several systems made, but the tests would have been of the illuminating and motive power required and other possibilities of the respective machines and lamps.

The Marenge, Trident, Ocean, Redoubtable and Hercules, ironclads of the French fleet, have recently been equipped with Gramme generators and Mangin projectors, furnishing 10-0 lights. The combined effect, at a recent naval illumination at Cannes, was said to be very splendid.

The Philadelphia Times thinks that the underground electric schemes were talked to death in the contest in the council having been between rival speculative enterprises. It is the opinion that no [illegible] privileges should be conferred on [illegible] ought to be given to any corporation whatever.

The keel is very much produced forwards, where, at its lower apex, it has a rough surface of some extent, against which the united clavicles abut. Sufficient material is not at hand for me to say whether xenicyanis ever takes place at this point or not: it may do so, because we find in Aluco these bones usually unite at this point; but yet we come across specimens of this owl where the union is no more perfect than it is here. The hypocleidium of the clavicles, and the manubrium of the sternum, are both about equally feebly developed. The upper extremity of each clavicle has a very broad abutment for the head of the corresponding coracoid, to the inside of which expansion these clavicular bones throw backwards a scapular process; but they fail to reach those elements of the shoulder-girdle, as we find them

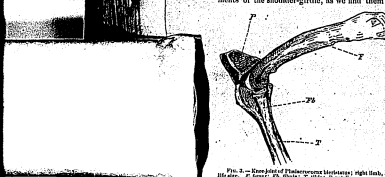

FIG. 3.—Knee-joint of Plusiocrocus bicetaceus; right limb, fifth size. *F*, femur; *Fb*, fibula; *T*, tibia; *Pt*, patella.

in others of the class. All of the bones of the pectoral extremity, or the arm, are completely non-pneumatic, but otherwise well developed. Faint papillæ for the quill-knobs of the secondaries are found along the entire length of the outer aspect of the ulna. The manus is composed of the usual number of bones,—one pisiform for index digit, two for the next, and one for the last.

In the lower extremity we find a femur of 6¾ centimetres in length; a tibia of 11¾; a metatarsus of 6; and the outer toe with five *foleata*, measuring in all 10.7 centimetres. This limb is likewise non-pneumatic, in so far as its osseous structure is concerned. The fibula is carried unusually far down the side of its companion bone, to within 1.3 centimetres of the lower periphery of the outer tibial condyle.

The greatest interest, so far as the bones of the leg of this cormorant are concerned, centres about the knee-joint. Here we find a condition of affairs which is presented in my drawing. The femur, which is much roughened above for the attachment of muscles, articulates about equally with the leg-bones. In front of this joint is placed a very large and massive patella, of a pyramidal form, articulating with more than half its lower surface with the anterior and lower fifth of the femur, its inferior and anterior margin articulating at the same time with the upper border of the cranial crest of the tibia. In front, we find that the groove that exists between the pro- and ecto-cnemial ridges of the tibia is produced on the entire anterior face of this patella, and, no doubt, the muscles of the leg are thereto inserted, as in many divers. Such examples as this throw some light on such birds as Colymbus and Podiceps, where this bone becomes anchylosed with the tibia in the adult. I have not the skeleton of a loon at hand, to examine the process spoken of by Professor Owen (‘Comp. anat. phys. vert.,’ ii. 83), and followed by Dr. Coues in his osteology of the same bird (‘Mem. Nost. soc. nat. hist.,’ i. pt. ii.), as the analogue of the patella. The skeleton I have of Podiceps to examine does not show it; but it is one that has been in my collection for several years, and may have been lost. Penguins have a very large patella, that articulates with the tibia much in the same manner as it does here in Phalacrocorax. Professor Marsh describes a very large, free patella for Hesperornis regalis, and remarks that it bears a general resemblance to that bone in Podiceps (‘Odontornithes,’ p. 30). In examining this bone in the young of our cormorant, it seems to ossify from one centre. The ossification at the summit of the tarso-metatarsus includes the prominent process at the upper and posterior aspect of that bone.

Many other points of interest are to be found in the skeleton of the adult, as well as of the young of Phalacrocorax idiersitatus, which space will not allow me to enter upon here: the leading points, however, I have endeavored to give, and these are always valuable when we wish to have them to compare with kindred forms.

R. W. Shufeldt.

THE ELECTRIC LIGHT ON THE U. S. FISH-COMMISSION STEAMER ALBATROSS.—I.

In pursuit of the hidden treasures of the deep, the work of the Albatross keeps her at sea many days at a time; and the operation

of dredging in great depths often carries the day's labor past midnight. To provide for these emergencies, which are frequent, and to afford ample illumination for the naturalists, not only in assorting the contents of the dredge as it is delivered on deck, but to illuminate their microscopes, delicate balances, etc., in the laboratory, the commissioner of fish and fisheries determined to employ the best artificial illumination the country afforded. As the vessel is essentially a steamer, using steam for every labor where it is practicable, the idea of electrical lighting from a dynamo-electric machine, driven by a steam-engine, was readily conceived, and an examination of the different systems was at once entered into. The Edison company for isolated lighting, we found, was prepared to enter into a contract for a complete plant, including the engine and the wiring; and being able to divide the light into eight-candle power lamps, besides giving guaranties, their bid was accepted.

The arc-lamp, though admirable for our deck, where a great quantity of light in a limited space is necessary, can never, from its great brilliancy, be utilized for twelve or fifteen naturalists, each at a special work, in the laboratory. It also occurred to the commissioner, that a lamp which could be lowered into the sea, to attract fishes, would be useful, thus affording another reason for preferring the incandescent light.

Fig. 1 shows the way in which the arc-lights are placed in circuit. And as each arc offers a considerable opposing electromotive force, it is necessary, in order to get light in a number of such lamps placed in series, to use currents of high tension.

Fig. 2 shows the incandescent lamps in multiple arc. The main wires, *a* and *b*, are tapped at pleasure, and the lamps are hung in the short circuits. The carbon threads in the lamps (described beyond) offer so much resistance that the current heats them to incandescence. The electromotive force in the circuit is low, which renders shocks impossible.

The plant on board the Albatross consists of an eight and a half hp. Ericsson and Sims engine, an Edison *Z* dynamo having its field-magnets vertical, a resistance-box in the circuit of the magnetic field, the main and branch wires, lamp-fixtures, safety-catches, and lamps.

The steadiness and uniformity of brightness of the lamps depend largely on the engine driving the dynamo; and the success of the system lies more in the attention paid to the engine, when the plant is correctly installed, than in any thing else. Uniformity of speed is the great object sought; and, to secure this, Mr. Edison has wisely adopted a high-speed engine with a sensitive governor, which is found in the Armington and Sims engine, represented in fig. 3.

The superiority of this engine lies in its well-

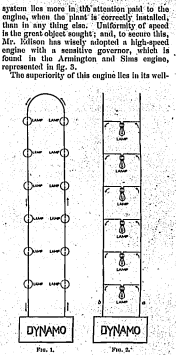

FIG. 1. FIG. 2.

balanced working-parts, its relatively large bearing-surfaces, its sensitive automatic governor, and in its simple and well-balanced valves.

To secure high speed without the noise of ‘thumping,’ great lap has been applied to the exhaust side of the valve, whereby ‘cushioning’ is effected. This cushioning, or early exhaust closure, also effects a saving by retaining, in the clearance spaces, steam which would otherwise have been exhausted and wasted. To prevent an unequal expansion between the piston-valve and its chest, the castings are so made as to allow live steam to surround that part of the chest which surrounds

the working-faces of the valve, as shown in fig. 4, in which S shows the steam space, and E the exhaust space. By this arrangement

FIG. 3.

the valve-stem is packed against the exhaust instead of the steam pressure. The valve is ground to a sliding-fit, and, so far as I can ascertain, there has not been a particle of wear or leak during the ten months the engine has been in operation.

The governor of the engine, that part which makes it especially valuable for the purpose of electric lighting, is represented in fig. 5.

This automatic device is fixed in the fly-wheel, which is keyed to the shaft. There are two eccentrics, E and F, the one within the other, and both free to move on the axis. There are two weights, with their centres of motion opposite, and fixed in arms of the wheel. These

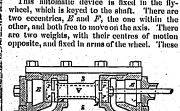

FIG. 4.

weights, W, W, are connected, each to an eccentric, and are connected together by an arm or rod. Springs are provided, to resist the centrifugal force of the weights. The system is so constructed that any centrifugal motion of the weights will throw one eccentric ahead and the other back, thus diminishing the throw of the eccentrics, and effecting a shorter cut-off without altering (within working limits) the lead of the valve. The engine used on board the Albatross has eight inches and a half diameter of cylinder, and ten inches stroke of piston: it runs without noise, three hundred revolutions per minute, requiring no more attention than the oiler can give it in addition to his other duties. When the main engines of the Albatross are in motion, a boiler-pressure of sixty-five pounds is often used, and twenty-six inches of vacuum is scarcely above the average. Lying in port, the boiler-pressure is kept at about twenty-five pounds; and, notwithstanding this great range of pressure, the governor regulates the dynamo to three hundred revolutions per minute, as closely as I can measure it.

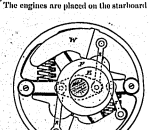

FIG. 5.

In selecting a good engine, Edison has, to my mind, displayed as much genius as in using the Siemens form of armature for his dynamo.

The engines are placed on the starboard side of the main engine-room, the engine taking steam from the main boilers, and exhausting into the main condenser.

The dynamo used on board the Albatross is

known as the Z dynamo, and is installed for what is called a 'tt circuit. It has its field-

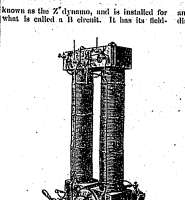

FIG. 6.

magnets vertical (fig. 6), and its armature revolves on a horizontal axis in the magnetic field. The field-magnets are arranged on what is called a 'derivation' from the commutator, placing it in the circuit, as in the Siemens system. In adopting and utilizing known principles and devices, Edison has worked out the details to a state of perfection simply admirable. Wherever the eye rests, it is pleased by correct proportions, sound mechanical ideas, and agreeable outlines.

The armature, on Siemens's principle, is mounted on a wrought-iron shaft. About the shaft, and concentric with it, are circular cylinders of wood, separating copper plates, as shown in fig. 7. Between the plates a and b, and also between a and d, there are annular disks of copper, insulated from each other. Between the plates b and c are similar but very thin annular disks of iron, separated from each other by tissue-paper. This built-up cylinder is then bolted together longitudinally; the bolts passing through the thin iron and copper disks without touching them, but clamping them between the thick plates. Wire bundles or bars are placed equidistant from each other longitudinally, around the cylinder, connecting each a pair of the copper disks, i.e., one at each end; and these bars or bundles generate the current.

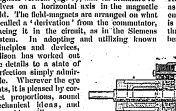

FIG. 7.

Bars of brass or copper, separated by thin sheets of mica, e,e, are dovetailed into the projecting end of the cylinder, which forms the commutator. The resistance of the generator is thus small, and allows great subdivision of the current in multiple arc.

To preserve the uniformity of the current, an adjustable resistance-box is placed in the circuit of the field-magnets; and, when a number of lamps are extinguished, additional resistance may be added to the field by a switch on this resistance-box, whereby the internal and external resistances are balanced, preserving not only the uniform brightness of the lamps, but also the economy of the machine. A test-lamp is suspended on the dynamo; and the fireman, who oils the engine, regulates the resistance according to the brightness of this lamp. Automatic regulators have been devised; but as it is necessary to employ a man to run the engine and dynamo, and as the incandescence is more frequently altered by slipping of belts than by the sudden turning-out of a large number of lamps, the same man can attend both to

consequently the simple resistance-box answers every purpose on board ship.

(To be continued.)

Globe, Monday, Dec. 17, 1877

ELECTRIC LIGHTING.

The most cursory reader of last week's news papers could not but be struck with the prominent place taken by electric lighting. If he glanced at the City article, he read day after day of new companies formed for the acquisition of one patent right or another, and would not fail to note the eagerness with which the public rushed forward to subscribe to the appeals made to them to take up shares in these several undertakings. Or, if, he confined himself to the general intelligence columns, it was simply impossible not to encounter the ubiquitous topic. At one time it presented itself in the form of a scientific lecture, at another in the more attractive guise of a marvellously wonderful results attained in the illumination of great engineering works, the lighting of a city, or, it might be, of a private house. That the subject has come within the sphere of practical questions, and very practical questions indeed, is abundantly evident. A Select Committee has been sitting for several days to take evidence bearing on the proposed enactments of several bills which are before the House of Commons, and though very different opinions have been expressed by the numerous witnesses examined as to points of detail, there is a general consensus of opinion that we are now on the eve of a change in our appliances for the production of artificial light as great as that which occurred more than half a century ago, when gas was beginning to take the place of oil and candles. There is this difference, however, between the past revolution and that coming one—that, whereas that was exceedingly gradual, this promises to be very rapid in its progress. The use of new inventions extends in these days with a celerity which was inconceivable even a very few years since. The telegraph came into general use but slowly; the telephone has become a necessity of life over half the world within half a dozen years of its invention. There are at the present time 17,000 Brush lights in the streets, to speak but of one system, 1,000 in the New York Central Station—and there is hardly a city in Western Europe or in the United States where one system or another has not been tried. In some instances, the experiment has been held to have failed, but the proportion of cases in which a considerable degree of success has been obtained is so large that no doubt can be entertained even by the most sceptical that lighting by electricity will before long be very generally adopted. It is another question—and one we are not now going to enter upon—whether gas is destined to be superseded. As far as experiments have yet gone, the probability seems rather to be that there are special uses for each of the two illuminating agents, and that whichever will probably be dispensed with for many purposes, there are others to which the new mode of lighting will prove less applicable, or for which it may be found too costly.

It is safer, however, as Mr. W. Spottiswoode remarked at a meeting at the United Service Institution the other day, to prophesy what electricity can effect in comfort. A Committee of the House of Commons, not many years ago, ventured on the prediction that the subdivision of electricity for use not to be hoped for. Both subdivision and conservation have now become familiar processes, and it may be that before long means will be discovered of adapting the force which already accomplishes such miracles of rapid bedding, or other directions to the achievement of results in the way of illumination at present undreamed of. Mr. Spottiswoode is himself among the most sanguine. He told the Select Committee the other day that he considered the experimental stage to have been passed, and that the scientific difficulties had been overcome, and that the only [illegible] of electric light [illegible] Edinburgh in his house and gardens. The incandescent lamp he regards as the best for the interior of a house, but prefers the arc system for use in the open air. Mr. Spottiswoode's evidence is, in fact, all to one effect. With regard to public buildings, he defends it on the grounds that it does not heat the room, and does not vitiate the atmosphere, while its colour is agreeable to the eye. On both these latter points there is room for difference of opinion. Some of the people who read in the British Museum probably complain of headache; and say that the dazzling brilliancy of the light is hurtful to the eyes. It must be admitted, we suppose, that the complainants are in a minority, for the trustees of the Museum, in their reply to the memorial lately presented to them by 200 members of Parliament, praying that the whole Museum may be electrically lighted, so as to be opened at night, say that the three years' trial in the Reading Room has been attended with "very satisfactory results." The trustees do not see their way at present to applying the electric light to the Museum generally, but we suspect they regard the application as only a question of time. They remark that, where the electric light has been introduced in other similar buildings, gas has been available either as an auxiliary or a substitute, but there are no arrangements for gas-lighting in the Museum, and it was would be hopeless to fix any objects in the collections. "The time has not arrived," therefore, they think, "when the galleries in Bloomsbury can be safely opened to the public at night." The meaning of this would seem to be that when the trustees have satisfied themselves by further experiment that such absolute reliance may be placed on electric lighting that gas may be safely dispensed with, either as an aid or substitute, they will consider the question again. In the meantime, we have not an estimate made of the expense of plant for lighting the whole building, and that will amount to a little more than £14,000. The Museum of Natural History at South Kensington might, the trustees think, be more safely experimented upon, and no doubt a little gentle pressure exercised upon them would lead to a trial being made in that building. The use of the electric light in dwelling-houses has other advocates besides the President of the Royal Society. Sir William Armstrong has tried it for nearly a year, and has lately published an interesting account of his success. Sir William obtains his power from a windfall nearly a mile from his house, and his only outlay, except on machinery, is the pay of the labourer who attends his machine. His lamp is the Swan, the filaments of which he finds by experience preferable to the arc system, therein agreeing with Mr. Spottiswoode. Sir William has thirty pairs of lamps, the light of each single lamp being equal to about 20 candles, and he praises the system alike for its efficiency and its economy. On the latter point the testimony given by Mr. George Lane-Fox, in his lecture at the United Service Institution, last week, was a little remarkable. Speaking of the Incandescent system, which by the by is a favourite of the Royal Society and by Sir William Armstrong, he expressed his conviction that a light of 1,000 candles could be produced by it, at the same cost as a gaslight of 12 candles—namely, a farthing an hour. This calculation, it may be observed, supposes one of the difficulties which occur to less sanguine people than Mr. Lane-Fox—the light of 150 candles is not wanted in any ordinary dwelling-house. Such difficulties will doubtless be overcome, but as far the experiments tried within doors have been either in public buildings or in large establishments like Mr. Spottiswoode's or Sir William Armstrong's, before we pass details of the success of electric lighting in the habitation to the interior of [illegible] Mr. Swan's house [illegible] Sir William Armstrong's [illegible] Mr. Spottiswoode's [illegible] Mr. Swan's

OLD ORCHARD ILLUMINED.

THE FAVORITE RESORT UNDER THE ELECTRIC LIGHT.

A Happy Party Goes Down to Participate in the Festivity.

The train which rolled out of the Boston & Maine depot at 6 o'clock last Monday, at half an hour past noon, had on it a special car which had been furnished by General-Superintendent James T. Furber, for the accommodation of some forty gentlemen, who had accepted an invitation to be present at the first illumination of that popular Summer resort, Old Orchard Beach, by the Pool Electric Light.

The invitations were issued by Mr. Edward H. Goff, President of the Pool Electric Light and Illuminating Company, whose plant less has been established at Old Orchard, making it the first beach in the country to be thoroughly illumined by the electric light. The company consisted of many well-known business men of this and other cities, and representatives of the press, and included, besides Mr. Goff and Superintendent Furber, Dr. William A. Hovey, second vice-president of the company; Col. Fred Mason, treasurer, and F. B. Stanley, general agent of the Bridgport Brass Company of Bridgeport, Conn.; Alderman George W. Fifield, Lynn; Mr. Henry Causey of the Cheshire Mills, Harmer, N. H.; Messrs. Martin V. Brady, B. F. Stevens and Benjamin A. Bilven of Thirteen Falls, Me.; Charles H. Cutler of Brewer, Me., dealers in mill supplies of that city; Mr. M. P. Curren, chairman of the Board of Selectmen of Scarboro; Messrs. Dr. J. G. Owens of Nashua, N. H.; Messrs. Dr. Charles H. Bean, C. B. Bean of the firm of Charles A. Smith & Co., merchants below, at Portland, Me.; A. Upton, general manager of the Jarvis Engineering Company of Lowell, Mass.; Messrs. Dr. Ellis Ames and Col. J. E. Bickford of the United States Electric Lighting Co. of Boston; Mr. A. A. Knowles of the Pennsylvania Railroad; Mr. Wm. H. Brown of the Baltimore & Ohio Railroad; Mr. W. G. Tallman of the Grand Trunk Railway; Mr. J. Tyson of the celebrated Armington & Sims Engine Company of Providence, R. I., who furnish the power to operate the works; Mr. H. E. Irving, manager of the Bridgport Electric factory, Mr. E. J. Welch, electrician, and Mr. C. D. Smith, the superintendent and engineer of construction of the American Electric and Illuminating Company; Mr. Joseph Wheeler of Lowell, Mr. W. G. Hassell of the Boston Evening Star, Mr. J. A. Sears of the Boston Daily Advertiser, Mr. J. Tyson of the Boston Herald, Mr. Henry O'Meara of the Boston Journal, Mr. L. H. Allen of the Boston Post, Mr. James S. Measham of the Boston Traveller, Mr. John H. Bradley of the Boston Newspaper Union, Col. Albert Clarke of the Boston Globe, Mr. Daniel O. Gray, G. P. Howell of the Boston Record.

The ride to the objective point was a most enjoyable one. The car was a new one, tastefully finished in cherry, carpeted with moquette and furnished with elegant cane arm-chairs with spring seats. Fruit and refreshments were furnished during the journey, and at Exeter, the "half-way" house of the journey, the minutes was made and refreshments furnished to those who had not partaken of them before.

Old Orchard was soon reached, shortly after 4.30 P. M., and the party proceeded to the Old Orchard House, where, after a brief rest, luncheon was served. To visit the lighting station is located near the beach, about half a mile west of the depot. Little more than three weeks ago this station was a plain, unfinished wooden building, 40 feet square, with its sills resting upon the sand. The company bought it, converted a basement for its boiler and furnaces, built solid brick foundations and piers for the support of its engines and dynamos, and in the interior placed and appliances of the plant, and finished the wood work outside and inside, making it complete. When the party visited it the mechanics were still at work and the merchant said: "You won't be able to get into this running order to-night, Mr. Goff." "Yes," replied that gentleman, "everything will be ready to turn on the lights at seven o'clock," and the result showed that he was right. After fully examining the station and its machinery the party was treated to a ride along the beach, which was one of delightful. Old Orchard is undoubtedly the finest beach on the Atlantic coast, at least north of Cape May. The breakers, noteworthy standing the calm sea, broke majestically, wave following wave with its white cap, rushing up the beach and, beneath the feet of the horses and the carriage wheels, and then receding to its own domain. Along the beach, as far as the eye could reach, were the people, and the beach lights, forty in number, and placed 4,000 feet apart, were in readiness to be lighted, making altogether a system of one hundred lights.

The plant consists of a steel boiler from the Charles River Works of Messrs. Kendall & Roberts of Cambridgeport, Mass., with the Avis furnace settings, supplying power for three Lawrence engines of fifty-horse power each (two of which are set and running), manufactured by the Armington & Sims Engine Company of Providence, R. I. These engines drive four dynamos of the American or Thomson-Houston system. The furnace consumes one and one-half tons of coal nightly to keep the 100 lights burning from seven to twelve o'clock, the hours during which they are in operation. This is the first time that coal has been thoroughly utilized as fuel by electricity. We read in the society reports of the weekly papers of bonfires by electric light—at this or that watering place; we have isolated lamps here and there. The Old Orchard system thoroughly illumines the whole place within an object measuring more than a mile long and half a mile wide.

The drive along the beach having been thoroughly enjoyed, the party returned to the Old Orchard House for supper, with appetites whetted to the keenest edge, the hour of departure from Boston having followed so closely upon the heels of business engagements as to prevent many from partaking of their usual mid-day lunch. That the supper was an excellent one goes without saying to all who know anything of this excellent hostelry that starred it.

As the sun sank to rest in the western horizon, evidences of festive preparation began to be manifest. Excursion trains from Portland, Saco, Biddeford, Salmon Falls, Dover and adjacent towns began to pour their crowded freights upon the platforms of Old Orchard station. Pyrotechnists were busy arranging their pastime of the festivity on the spacious lawn in front of the Old Orchard House, a lawn that slopes from the broad piazza down to the street and even to the beach, the breakers and the open sea. At about quarter past seven, when the shades of night began to settle down, the electric current was turned on and one and all started, the pioneer in this respect, was lighted as was anything else that was once lighted before.

Meantime the guests of Mr. Goff and his associates, who had accidentally arrived at the latter men and had strolled about the piazzas or the lawn for a short time, were again called together to take carriages for a drive along the beach. But the long trains conveying their throngs of people upon the scene somewhat impeded the way and it was decided to wait until later. The guests therefore took their positions upon the piazza of the hotel and witnessed the finest display of fireworks ever given in the State of Maine. They were from the laboratory of Messrs. Mason & Wells of Boston, and consisted of flights of rockets discharged from mortar points, fire balls of different hues, gold and silver rain, and amber streamers, showers of blue lances and balls of dragon and gold bombs, gold and red streamer balls. There were several set pieces, including stars and crosses. One device was that of two stick skaters, life size, on skates, and the display closed with the set piece, "American System of Electric Lighting," in varied and beautiful colors. To Gods what a sight it was. Probably 20,000 people witnessed it. The grounds of the hotel were crowded, the stairway and platform leading to the railroad depot were crowded, the lawn in front was crowded and the roads were filled with teams and pedestrians.

The magnificent skating rink was like a vision of fairyland, the walls inside literally covered with Chinese lanterns in brilliant hues and gorgeous fluorescence, while the excellent band furnished music for the merry skaters. Fully fifty people were turned away from the rink during the evening, unable to gain admission on account of the crowd. Chandler's Band of Portland furnished the music on the lawn previous to, and during, the fireworks. And away beyond was the magnificent beach, its broad and shining sands stretching down to the glorious breakers, all as plain in the electric brightness of the electric light, at a distance of nearly half a mile, as it had been at noonday. The weather was all that the most exacting could have desired. Even the moon seemed to respect the occasion, and kept herself veiled behind a cloud until after the fireworks were finished.

Among the guests present were Governor Hobbs of Maine, and several members of his staff, the mayors of Portland, Saco and Biddeford, with their respective boards of city government; City-Marshal Andrews of Portland, and many prominent officials and citizens from that and other cities. Notwithstanding the immense throng, there was no disorder and no disorder. Everything was as peaceful as could be wished.

After the fireworks, the party of which it was the GAZETTE'S good fortune to be a member took to the carriages once more, and visited the lighting station to see the working of its practical operation. And what a sight it was! Everything, though started then for the first time, was in as perfect running order as if the plant had been in operation for years. Not a jar or a slip occurred. "There was Mr. Ellis, the builder; of the engines, in his shirt sleeves, personally superintending the work, and examining with the eye of a master every detail of their operation. He found no "screw loose," of course, as any one familiar with his work can readily believe. The wheels of the engines were running at the rate of 300 revolutions per minute, and the dynamo machines 850 per minute, but so smoothly did the engines work that there was no noise, and scarcely may be in the door. The term "illuminated lightning" will apply literally to the production of these engines, for it is but a step from one such as order to create the power which makes the electricity and sends it over the copper grasses over the four corresponding circuits.

After a full inspection of the practical working of the enterprises another drive over the beach under the light of the forty lamps was enjoyed, and it was the sensation of a lifetime. Words cannot describe the beauty of the scene—it must be left to the imagination. The sea lashed, and the sand glorious light, rivalling even that of the sun, in the distance, and the road, with its majestic breakers, rising, falling and shedding their silvery spray. Between, the magnificent beach, broad, smooth and glorious—a very abreast upon which could have almost driven four horses.

But nature will assert itself, and man must eat. So the party returned, almost reluctantly, to the hotel. Now it was with the others was seated, but we do know that the GAZETTE retired, and slept the sleep of the unbelievers, and have by a single exception, who was speedily discovered and knocked out.

In the morning a hearty breakfast with trimmings from the farms of the Messrs. Hanson, on account of the crowded condition of the hotels, being distributed among different ones for the night), and to the train for Boston at 9.30. The same car that brought the party down was boarded and the ride was a repetition of that of the day before. At Dover the Boston train was boarded, aboard and were eagerly scanned, to see what had happened in the night in the glorious town.

A portion of the party, inspired by the irrepressible Furber, of the Baltimore & Ohio, made merry music at one end, gilded by Jim Pinafore, at the other end of the car, and sliding into jubilee melodies with perfect recklessness.

Boston was reached at about 2 P. M., but before a benevolent dispensation of Dr. Goff had been drawn up and signed by every member of the party. Following is a copy:

We, the undersigned, members of the excursion party to Old Orchard Beach, Me., Monday, Aug. 15, to witness the opening and putting into practical operation at that place of the new electric light system of the American Electric and Illuminating Company of Boston, desirous of showing our appreciation of the courtesies extended on that occasion by the genial and hospitable president of the company, Mr. Edward H. Goff, hereby tender our individual and collective thanks to that gentleman, and earnestly hope that the great success of our success that has attended him in this vast undertaking may be but the earnest of success through life. That merit will always come uppermost. We, one and all, vote Edward H. Goff a "prince of good fellows," an efficient officer, and identified with an enterprise that will prove to the future to be a blessing to his whole human family.

Mr. Goff was indefatigable throughout the day in his duties, and he made the party happy, and he was ably assisted by other officers of the company. More than word of thanks is due, however, to Superintendent Furber of the Boston & Maine Railroad for the splendid accommodations his facilities, but then, that is what might have been expected of him. He has a head in it. The company separated, after many handshakings and good-byes, hoping that the chance for a repetition might, in the course of human events, present itself ere long.

The success which has attended the lighting of Old Orchard will doubtless lead to the illumination of other resorts by the American Electric system. It is an electric avenue, and it is a strong one, and the thin end of it is very thick.

THE BRIGHTNESS OF LIGHT IN THE CITY.

To the Editor of the Manufacturers' Gazette.

SIR,—In the report of the proceedings of the Commissioners of Sewers, which appeared in your issue of Wednesday, June 23rd, the minimum charge for electric light per hour for the month of May is stated to be 2.0357c., and the maximum 1.2667c. Now, sir, I am a subscriber to the Incandescent Company's system, and this is upon a wrong basis, perhaps analysis of the figures will show that I am the highest contract tenders received for the three sets, and the lowest tenders received for the principal reason being that I myself as follows: Each set of lamps is supplied with a switch, by which the current can be turned on or off at pleasure, and the consumption of electricity is registered by a meter. Now, sir, I do not object to anyone knowing my business, but I do object to the unnecessary comments. For obvious reasons I will not state the name of the firm which I supply, but will number and mention them in sequence according to their tenders.

THOMSON-HOUSTON OR COMPARATIVE COST OF ELECTRIC LIGHTING PER ONE YEAR.

Schedule No. 1, comprising Norman-street, Gilbert-street, Hill-street, Dundas-street, Clarence-street (from Hill-street) and Clarence-street (from Dundas-street to St. Martin's-le-Grand), Queen-street (from Cheapside to Bucklersbury), and Queen-street (from Bucklersbury to Dowgate-hill).—Estimated annual cost of present gas lighting, about £311; the Jablochkoff system, £1,000; the Brockie-Pell system, £1,000; the Siemens system, £1,000; the Thomson-Houston system, £1,000; the Swan system, £1,000; the Edison system, £1,000; the Crompton system, £1,000; the Lane-Fox system, £1,000; the Gramme system, £1,000; the Brush system, £1,000; the Wallace-Farmer system, £1,000; the Weston system, £1,000; the Maxim system, £1,000; the Ferranti system, £1,000; the Hopkinson

discovery. First, it is a continuous line adjacent to one already lighted by the Anglo-American Brush Company, all the cables from premises or station permanently established for the manufacturing of the Brush machines, the pavements and carriage-ways not presenting any considerable difficulties encountered in No. 3 District; the width of the streets not being so great, nor with any of the obstacles as found by Messrs. Siemens. Another point in No. 1 District is that the gas lamp posts were used, therefore another great saving in the first outlay. With respect to the illuminating power I believe that there is a difference of opinion among the scientists themselves with respect candle power. Messrs. Siemens stated that they gave sufficient light to their district; whilst if more was given by the others it was wasted.

As to the Brush Company "deliberately refusing to tender" for other districts, the answer is they could not, having sold or granted concessions to other companies; with respect to No. 2 District, the same arguments apply as to No. 1 and 3, only in a less degree.

Now, sir, as regards the great difference of price in each district. It is like making a mile of railway through a hill, and one through open meadows. As regards the future cost of maintenance and production of the electric light, eminent electricians say that it will be far cheaper than gas. That is a question I am not able to speak on, but this I would venture to say, that if the local authorities would but lay down the "permanent ways" for the electric light, giving to all private houses and establishments on the route every facility to have their premises lighted, so that electric companies contracting would only have to thread their cables through, and lay down their own machines and at the end of their term they could take up their machines and take out the cables, the less would then be titling monopoly.

The local authorities and their officers would be by far the best persons to carry out the laying of pipes, being accustomed to, and fully aware of every difficulty that is likely to arise, and they would keep a bold open the light of the future such as they ought now to have on the water supply of the metropolis.—I am, &c.,

ONE WHO KNOWS.

TO THE EDITOR OF THE CITY PRESS.

SIR,—My attention has been drawn to a short report of a meeting contained in your issue of June 14th respecting an opposition of Mr. Siemens's system of electric lighting. In the condensed form of your report when I actually stated less to some extent becomes inaccurate. I said that I had been associated in duties with Mr. Peter McKillop, of the Royal Arsenal, some 20 years ago, in connexion with the production of electricity for the purpose of firing guns at proof, and that the present form of incandescent lamp was identical with that introduced so long ago for artillery purposes. Further, that Mr. McKillop invented, and that I myself had worked at proof of guns, exactly the same form of switch as those now in use for electric connexion and disconnexion, for lighting and other purposes, therefore I could claim to know something about electricity for many years, particularly as it was a subject which I had ardently studied and switched in all its aspects since the period in which I had been gained an insight into it.

I write this note to you because your condensed report has caused somebody to take undue upon him by the *Electrical Review*, which paper, in a sneer, wants to know what connexion there is between firing guns and electric lighting. Perhaps you will allow me, through your paper, to say that I think there is some connexion between the two, since the same generators and currents for firing guns on board our ironclads that you have that which is now and is destined to be so very useful, safe, and economical on all our men-of-war. The *Electrical Review* does not seem to be aware that the generators which gives that powerful light for the discovery of the advance of the torpedo-boat at night, fires the gun with which this is swept of naval warfare. There is the cadet who passes out of the Royal Military Academy at Woolwich for the Royal Artillery or Royal Engineers, that is "not well instructed in all the principles of electricity, including lighting, and who is well able to take charge of any service or otherwise, whenever the opportunity arises."—I am, &c.

Journal of Gas Lighting, Water & Sanitary Article, June 16, 1882

ELECTRIC LIGHTING MEMORANDA.

THE anticipations of those who looked upon the Electric Lighting Act of 1882 as premature will probably be regarded by them as justified by the fact that only four applications for the present year, involving a total capital expenditure of £200,000, have been received by the Board of Trade for Provisional Orders under the Act. Last year there were 100 applications, the great majority of which were rejected or allowed to drop; and not one of those that were finally granted has been put in force. There are spasmodic displays of scanty electric lamps in districts for which statutory powers were obtained; but as not one of them is on a scale that could not have been attempted without formal permission of the kind, the utility of the Act may well be called in question. The very fact that a law ushered in with such a flourish of trumpets should, in the second year of its existence, so invoked by four applicants only—and half of these asking merely for the transfer of Orders previously granted to others—is a luminous illustration of the extent of the need for it. Although in the positive sense of facilitating or fostering a business in electric lighting the Act is a failure—simply because the business which it was intended to regulate has no existence—it has been successful in preventing a great waste of money in the attempt to force electric lighting into unnatural favour. There can be no doubt that but for the fear of the Board of Trade, and the question of coal deposits, bubble Companies into existence, and have struggled on for a year or two, not without causing trouble and entailing expense on the ratepayers and residents of the places favoured by them. Instead of this, the Act has confined the game to Local Authorities with more ambition than wisdom, and the Companies who could show that they at least had some money to spend. How many of the latter will survive to make use of their shadowlly defined charters, or how many of the former will grow tired of their useless privileges before these become duties, remains to be shown.

A very neatly worded account of the electric lighting of the libraries and dining-rooms of the House of Commons with Edison lamps appeared in *The Times* of the 14th inst. The engines and boilers, connections and fittings, are described with great care, and the impression evidently intended to be conveyed by the paragraph is that no expense has been spared in making the installation complete in every respect. The notice contains this sentence: "Ample provision has been made against any failure of the light, from accident to the engines or machines." This is what *The Times* says; hence it is only natural that inquiry should reveal the fact that on Saturday, the 9th inst., the *Pall Mall Gazette* contained the following paragraph:—

> The occupants of the reading-room of the House of Commons had a very exciting evening adventure on the occasion of the electric light going out, without the slightest warning. The whole place was thrown into total darkness, the honourable members are said to have "rushed from the room under the impression that something dreadful was about to happen."

Comment is superfluous.

At last a decision has been arrived at in the case of the Metropolitan Brush Company. The proprietors have determined to wind up the concern, and to try how much money they can recover from the promoters. The Shareholders' Committee have carried everything against the Directors; and, among other things, the Holborn Provisional Order will be thrown overboard. The Directors clung desperately to this Order, as well they might, for it is the only thing they could show for the quarter of a million sterling or thereabouts that has passed through their hands. They obtained, at the Annual Meeting, a resolution declaring that, to carry out the Order

and provide lighting at the cost of gas would result in a profit of 8½ per cent. On the other hand, Mr. Robert Hammond (who, of course, had a finger in the pie) told the shareholders that the Order could only be carried out at a loss of more than £9000 per annum. If anything done by the fact that, after stating this opinion, Mr. Hammond offered to buy up the whole concern, for the Company that bears his name, for £80,000 in 6 per cent. debentures, and £30,000 in 5 per cent. deferred shares, or instead thereof the round sum of £80,000 in cash. Considering that Mr. Hammond's own connection with the promotion of the £30,000 a concern which a few months ago paid £286,000 for patent licences alone, was rejected with contumely in favour of the resolution to voluntarily wind up the Company,

ELECTRIC LIGHTING MEMORANDA.

The time has come for the deposits of capital to be made with the Board of Trade in respect of the Electric Lighting Orders granted last year. Within six months from the date of confirmation is the time appointed under the Act; and this period having nearly expired, the various Companies are now casting about for excuses to obtain an extension of time. Among others, the South Staffordshire Electric Lighting Company—one of the Brush swarm—have an Order for lighting Wolverhampton; but, of course, they are not ready to begin, and so they ingeniously ask the Board of Trade to give them other six months' grace, while they can watch how the Consolidated Electric Lighting Company (another set of the Females) get on at Colchester. Considering how many times the world has been assured that electric lighting —and especially the Brush system—has passed the experimental stage, it is odd that the Wolverhampton speculators still find it advisable to wait upon Colchester. Of course the Town Council of Wolverhampton are assured by the local speculators that there is not the least doubt of the result, but still it will be better to wait and see. Strongly enough, the Town Council do not appear to understand the position; and therefore they have successfully opposed the petition for an extension of time, with the probable result that the Wolverhampton Order will be revoked void six months earlier than it would otherwise have been. There is some show of indignation in the district in connection with this matter, now directed against the Town Council; but this feeling will probably turn against the real culprits when the true state of affairs is better appreciated. It remains to be seen, in the other cases of application for extension of time for deposits, whether the Board of Trade will prolong the agony, or make a clean sweep of the original Companies by demanding the prompt fulfilment of their financial engagements. It is idle to pretend that the cause of electric lighting will be served in the long run by continuing the existing Provisional Orders in the hands of those who have neither present means nor prospects of doing anything.

An extraordinary general meeting of the Gilcher Electric Light Company was held on Wednesday last, when the proceedings deserved the publication of "extraordinary" in the limited to the meeting was for the purpose of authorizing the Directors to accept surrenders of shares, and to make other arrangements which will eventually reduce the capital of the Company from £106,000 to £90,000. It was stated that the Independent Committee have been at work during the past three months upon the arduous task of reorganizing the Company's affairs. The work has been so successful that one may picture the hardly-used shareholders of the Metropolitan Brush Company, who are just beginning a similar enterprise, blinding themselves by solemn oaths not to stop until they have attained equal fortune. Briefly, the promoters of the Gilcher Company have redeemed £70,000 of the £100,000 paid for the patents, and the original patentees have also given £80,000 of the purchase-money. Besides this, a saving of £200 a year has been effected in the item of rent; the Consulting Electrician has deferred for five years the annual fee of £1000 a year, have been arranged. It will now only require a clear profit of £6000 to pay a 5 per cent. dividend on the reduced capital, instead of £12,000 as formerly. Whether there is really any better prospect of earning the one than the other is very certain. The Directors announce that they are doing a considerable amount of lighting in different parts of the world—one installation being at Lyttelton Harbour, New Zealand, in succession to the Brush Company. The most important installation, however, is that at the Crystal Palace, where 72 arc lamps are to be maintained at a price which the Gilcher Board describe as directly profitable, but which the *Electrical Review* has stated to be "considerably lower than many well-informed engineers consider a remunerative one." This Gilcher lighting prospers.

The petition of Messrs. Peebles, Sir Edward Ingledeu, and Co., for winding up the Metropolitan Brush Company is fixed for hearing on the 7th inst. by Justice Kay. This is more than the "beginning of the end" of the largest of the concessionary Brush Companies; it is the end itself. The Board of Directors ceased to act at the termination of the last shareholders' meeting; and therefore the Company, as a going concern, became extinct at the same time. It has been repeatedly urged on the part of the Board that the Provisional Order for lighting Holborn should be proceeded with, on the ground that it would be so profitable that it would pay to keep the whole machine going for this particular purpose alone. The Shareholders' Investigation Committee did not take this view; but—apparently in order to test the good faith of the Board—they offered to take up the work on behalf of the proprietors, or to try and dispose of the Order, for which they had been assessed "money had been offered." The proposal was declined; from which it appeared that the real object of the Directors, in putting forward the imaginary advantage to be derived from this Holborn Order, was not so much a desire to do the work as to keep the game up a little while longer in their own hands, by making this their excuse. If they were not allowed to carry out the Holborn Order themselves, the Shareholders' Committee should not do so, however profitable it might appear. Hence it is not to be wondered at that the proprietors—to whom this little plot was exposed by one of their own Committee—declined to allow such a Board to continue in office any longer, especially as the cost of maintaining the Directors and staff amounts to £8000 a year, which, if allowed to run on, would soon eat up the present dispondent cash balance of £30,000.

ENGLISH MECHANIC AND WORLD OF SCIENCE.

THE ELECTRIC LIGHT IN THE CITY.

WE gave on p. 289 of Vol. XXXII. a somewhat lengthy account of the experiment to of the alternating machines are also excited light in fog; the effects, if any, of lightning short account of the experiment to of the alternating machines are also excited light in fog; the effects, if any, of lightning be made in the City of London with the concessionary Brush Company's machines, and also of the current from a small dynamo will be witnessed; and lastly but not least, we electric light—an experiment which it is considered will have a most important effect on the progress of the "new" system of lighting. It will be remembered that one of the streets were excepted from the compulsory taking over by the Brush Company, and that though Crompton's is not adopted, we may be satisfied that there will be no needless trial of an already well-tried system. The Brush system extends from the Surrey end of Blackfriars Bridge, along the north side of Bankside, Southwark Bridge along Queen Victoria-street to Blackfriars Bridge is to be 22,000 feet for the 250 days during which the experiment is to last. The machine-house, with engine groups, each with its separate steam-engine, and a third engine in reserve. The machinery supplies current for six powerful lights, varying light about, at night, 4000 candles; for the larger as much as 6,000 candle-power. Each of these lamps has its own dynamo machine, while the 28 smaller lights are worked by two alternate-current machines each having 14 lamps. The lamps have double carbons and, in two groups of seven, are so arranged that, if either one of them should be burning too brightly, the other will be shaded from the full power of the current, so as, above this point, to reduce the light. The carbons in all the lamps are placed with copper, there is the largest lights being 2½in. long and ⅞in. in diameter, the negative or lower carbon being smaller. The other lights being worked by alternating currents, the carbons are both of the same size, being 1⅝in. long by nearly ½in. (0·5in.) in diameter. As to the photometric value, the estimate is that the small lights, 2

THE EDISON ELECTRIC LIGHT INSTALLATION IN NEW YORK.

WE have previously mentioned that the Edison Company were laying down mains and fitting up wires for an installation of the electric system of lighting over about one square mile of the business section of New York. The district includes 950 subscribing consumers whose premises are already wired, the number of lamps in which is nearly 14,000. About one-third of the whole area has now been working for some days; but before all the subscribers in the square mile can be accommodated, the plant must be nearly doubled, as each generator is equal (in practical working) to only about 1,200 lamps (nominally 1,800), and at present six dynamos only are ready. About fourteen miles of street mains have been laid; and the experiment, so far as more than yet reached this country, is a success, about 7,000 lamps being steadily supplied, including those at some of the newspaper offices. The central station is situated in Pearl-street, a short walk from Fulton Ferry, the building itself being merely a shell inclosing the platforms by means of which the apparatus is placed. The building is about 50ft. by 100ft., and is divided by a middle wall into two equal portions, one only of which is at present occupied by plant. Originally erected for commercial purposes, it was quite inadequate to support the great weight of the machinery, and as it now forms merely a shell, the new interior which is composed of iron pillars and girders resting on a substantial base of concrete. The boilers in the section at present working are four in number, of the Babcock and Wilcox type, each being of 250 horse-power. These boilers are of the water-tube class, having long inclined tubes set between external walls, and each with a shell reservoir, the bottom of which is exposed to the direct rising heat of the tubes. The fronts are completely finished in white enamelled brick, the footwork is used as the doors for coaling, and engine of about 20 horse-power is placed there for working a fan to supply air to the furnaces, and keep up a draught. Coal, which, at the same time, by means of screw conveyors, it keeps up a constant supply of coal to, and removes the ashes from, the stokeholds. The boilers being arranged on opposite sides, the firemen have only a short distance to walk to reach the coals, and the place is kept as clean and tidy as possible. Each boiler has an injector, and one large steam-pump is so fitted that it can supply any or all of the boilers. The feed-water is heated as far as possible, by being forced through a feed-heater which receives the exhaust of all the engines. The object is not merely to secure the greatest degree of economy of heat, but also as far as possible of the impurity of the water before it reaches the waterbottom of the boilers. The steam is taken by an 8in. pipe, from which 3in. pipes rise vertically to the engines on the floor above. Each dynamo has its own engine on the same base-plate, the combined set weighing nearly 20 tons. The engines are of the Porter-Allen type, with cylinders 16in. diameter, 24in. stroke 160n. The cut-off is regulated by the governor, the engines being set to run at 350 revolutions, with a pressure of 120lb. per square inch. The connecting-rods dive direct on to comparatively small disc flywheels carried on shafts coupled directly with the armature shafts of the machines. Some idea of the enormous dimensions of the dynamo may be gleaned from the following figures:—Length of armature, 5ft. 10in.; diameter 2ft. 2in.; weight 9,000lb. The field-magnets, of the horizontal pattern, weigh nearly 15 tons, and the height of the machine from floor is 6ft. 5in. The resistance of the armature is .0028 ohm., and the current of so low an intensity that it can cause no injury to anyone inadvertently handling or touching the wires. The six dynamos are arranged in a line on one side of the room, and are alternately connected to the heavy copper bars forming the main leads on opposite walls, the bars of like sign being connected together at the front of the building, where the entire the current is collected into two large horizontal copper bars with which the leads laid under the streets are coupled. These street-mains vary in size, some of them being equal to a copper rod of about half-inch sectional area, while others are equivalent to about ten wires of No. 10 gauge, and others again so relatively small as to equal only about two No. 10 wires. The leads, except where they diminish to the size of wires, are of nearly semi-cylindrical section, and are placed in iron tubes which are filled in with insulating material. Here and there are service-boxes, in which the leads are so shaped that they serve the double purpose of taking up expansion, and allowing for contraction, while affording a ready means of making connection with the wires which convey the current to the wires which supply the consumers. The regulating apparatus consists of a circular switch and a number of resistance coils, and is so arranged that the attendant to judge of the strength of any dynamo has the field-magnets, it should be mentioned, are in shunt with the armature, and which can be increased from a function of an ohm to seven and a half ohms, which is the greatest resistance necessary to control the current used for excite the field-magnets. The circular switch is operated by a horizontal shaft through sets of mitre gearing, and the indicator is an ingenious arrangement by which unskilled labour can be utilised for regulating the current. When the indicator consists of a couple of lamps, one of blue, the other of red glass, neither of which is illuminated when the current is normal. The electrical arrangements are so made that when the resistance of the shunt circuit is too small, the blue lamp is illuminated, and the attendant turns his wheel in the direction in one constant circuit after another until his blue lamp goes out. If, on the other hand, the red lamp shines out, the switch is turned in the opposite direction, and the resistance in the shunt circuit is increased. The dynamos work on the same circuit normally, but each is provided with a switch for cutting it out. This switch consists of a couple of bars pivoted at one end, and which a cross-bar carries three plates, about 1ft. long; which can be brought down between three pairs of fixed contact-plates, each pair thus closing, as it were, one of the plates on the movable lever. A pressure-relieving tends to force up the bars from the movable portion of the switch, and a catch keeps it in position when the plates to which it is brought are required to be in the circuit. If there is any reason to suspect that a dynamo is not doing its proper amount of work, a touch on the key of the switch at once causes the needle to arm, which flies up and breaks the circuit. The suspected dynamo is then connected to the test battery of league, 1,000 in unit, which is erected in one of the towers on the top floor, and if it raises those to a state brilliant incandescence, the machine is credited with being in proper order, and is supposed what must be looked for elsewhere. The machine, as we have mentioned, possesses a nominal capacity of working 1,800 lamps, but it is not intended to have more than just 1,200 lamps to at once; hence, if one unit raise the to brilliant incandescence, it is in a condition to start in full capacity. The normal condition of Edison's lamps is just short of what would be termed brilliant incandescence. The reason the dynamos not worked up to what is alleged to be full capacity can be easily gathered from what we have said. At present, the bulk the generating establishment is supplying the electrical of the whole area is lighted. When the other half is coupled, as we may assume that it has been will be able to supply the 14,000 lamps, now wired; but already there is no reserve in case of accident to one of the machines. The engineering has been provided for, it is alleged fact that the machines are capable of working more than 50 per cent. above their rated power. Given only one machine at the station, and one lamp on the circuits, and the current would be delivered to the latter in many places, for it is nearly and pure, and while scarcely heated the air, certainly does not vitiate it by the presence of a number of carbonic acid. Should sundry defects will be discovered before arrangements before many weeks are although it must be acknowledged that the Edison and Swan lamps are working well, and have endeavoured to make the installation as complete as possible in every detail. We have heard of some defects in the insulation of the main leads, and the New York people may be relied upon to imagine some exciting fearful freaks of the "electric fluid" on the present the installation has settled down to ordinary work, and as the plant on the large scale, it will unquestionably of great advantage to the engineers of similar installations, especially if, as is to be hoped, they will favour us with accurate accounts of the actual cost are published.

THE ELECTRIC LIGHT IN A FRENCH WORKSHOP.

THE electric installation at the railway works of Saint Denis is pronounced by *Le Moteur* one of the best examples that could be cited of the great variety of applications of which electricity is susceptible, and the numerous services it may render when judiciously employed.

The workshops and sheds of Saint Denis are exclusively—at least in the part lit electrically—devoted to the construction of railway carriages. The numerous machines located in this manufactory are driven by a seven-engine of 60-horse power, of which there is always at least, 10 available (otherwise) during the whole time of work, but the nature of the work does not allow of taking more than 10 in a permanent way at any moment; and yet this available force would be insufficient for lighting the workshops, which is effected with 70 arc-lamps of the Weston system, and 24 Maxim incandescent lamps; representing, when the whole is in operation, a work of 15 to 16 horse-power. This difficulty has been got over by the use of accumulators in the following way:—The dynamo electric machine which, in the evening, feeds the Weston lamps, serves by day to charge the accumulators, which, in the evening are discharged through the incandescent lamps. Thus, the available work of the engine is utilised throughout the day, and a single dynamo-machine suffices to supply the whole lighting service, which is then established under the best economical conditions.

The accumulators employed in this installation is a combination of the Faure and the Sellon-Volckmar system, with inductors in circuit. Its furniture, which consists of 220 accumulators, an electro-motive force of about 250 volts, and a current of 200 ampères, is found sufficient to feed 10 lamps in circuit, which is less than 25 effective volts per lamp.

By day, the machine-current is sent into the accumulator with gathered plates of the Keiath system, arranged in two series of 30 elements each. A two-direction commutator allows of changing the course of the current at will, in the Weston lamps, or to the accumulators. The arrangement of the machine requires, in this latter case, some special precautions. It has been stated that the inductors of the machine were placed in the same circuit. It results from this that if the machine were directly shunted to the accumulators, at the moment of charging, the current of them would increase the excitation, and consequently the current produced in the machine, and the effect of this would be to quickly *complete* the accumulators, instead of filling them, and perhaps they would be damaged. The following method is adopted to obviate this:—The circuit of the machine is first closed through a number of sulphuric acid voltameters, of the same kind as those which serve

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT
229 BROADWAY, NEW YORK.
P. O. Box 2898.

SATURDAY, APRIL 30, 1881.

Since we last referred to Mr. Edison and his incandescent lamp, the subject has been advanced another step and the final stage of complete and unqualified success achieved; permission has been granted to the Edison Light Company, to place surface conducting wires under the streets of New York City, and in the course of the next two or three months one large district of that city will be enjoying the full benefits of Mr. Edison's system of electrical illumination.

Taking a retrospective review of public utterances on this question during the last eighteen months, we now extend our condolence to a certain class of professed scientific experts who have maintained, from first to last, the impracticability of Edison's well-devised plans.

Never in the annals of scientific discovery has a grosser attempt been made to pervert the truth, and mislead public opinion.

As one instance among many, let us take up what is offered as a standard work of reference on this subject: "The Electric Light, its Production and Use, embodying plain directions for the working of galvanic batteries, electric lamps, dynamo-electric machines, etc," by J. W. Urquhart, C. E., edited by F. C. Webb, M. I. C. E., M. S. T. E., London, 1880. Under the heading of "Edison's Lamps" we find "much interest has been taken in the sensational and often absurd announcements, concerning apparatus in course of perfection by Mr. T. A. Edison, of Menlo Park, New York (?), and it was in *some quarters* thought, that when he had set himself about the task of inventing an efficient subdivision of the electric light circuit, *something* would in all probability be done."

"There is little probability, however, that this lamp (the horse-shoe carbon), will prove constant. Burnt paper in various forms has been repeatedly tried before, and it is assuredly not constant, in the best possible vacuum obtainable." "We may indeed rest assured, that upon further reflection, Mr. Edison will abandon this imperfect burner." The same authors in speaking of the "Sawyer lamp," describe it as "the best incandescent lamp of this kind that has been invented."

Such being the teachings of an educational work, written by professed teachers on this subject, let them be compared with the actual results achieved, and the relative positions of the two men at this moment. Seldom has the irony of events demonstrated more forcibly that the honest work of a man is proof against the assaults of fraudulent or ignorant critics, and that the leveling influence of time always reveals the truth.

On the various attempts to imitate Edison's lamp we shall offer but a few words, for most practical inventors are usually plagued by men who endeavor to duplicate their successful inventions. If "imitation is the sincerest of flattery" we suppose Mr. Maxim is merely desirous of paying Edison a high compliment. Concerning Mr. Swan, of Newcastle, England, who professes to have perfected a horse-shoe carbon lamp, apparently identical to that of Mr. Edison's, we would draw attention to the significant fact, that in Messrs. Urquhart and Webb's work on the "Electric Light," dated as recently as April, 1880, and published in Mr. Swan's own country, not a single reference is made to the Swan electric lamp—in fact, his name does not occur in the book. This would appear to be conclusive evidence that neither Mr. Swan, nor his lamp, were known in England up to that date—unless he is included among the nameless crowd, spoken of by the authors, who had "repeatedly used burnt paper in various forms," and who *failed to secure constant results, even "in the best possible vacuum obtainable."*

were of special interest; earthquakes were reported in New Hampshire and California on the 19th, and in Maine on the 21st.

HISTORY OF THE APPLICATION OF THE ELECTRIC LIGHT TO LIGHTING THE COASTS OF FRANCE.

I.

THE value to navigation of thoroughly lighting our coasts is too evident to require any argument in its favor; and, in view of the immense interests at stake, there is no question but that improved methods of lighting should be adopted, almost regardless of expense, providing that the advantages gained are in any way commensurate with the cost.

France has long appreciated this; and it is to her that the world owes the Fresnel lens and many improved lamps burning successively whale, vegetable, and mineral oils. She has finally led the way, as usual, in the use of the electric light, which has been definitely adopted for the lighting of her coasts, after many expensive and conclusive experiments; and, when the plan has been fully carried out, France can boast of having the best and most systematic method of coast-lighting of any country in the world.

The United States has followed France. Our optical apparatus has been almost exclusively imported from that country. We use lamps made after French patterns, and now we are making experiments to determine its value for our lighthouses. This is deemed sufficient excuse for giving full details of the French system. The information has naturally been mostly obtained from French sources.

It was in 1863 that the electric light was for the first time used in lighthouses. The experiment was made with an Alliance machine in the first-order lighthouse of la Hève, near Havre; and the results were so satisfactory that doubtless all the lighthouses would have been immediately furnished with electric lights, had it not been for the great expense attending a general alteration. It was proved that the electric light was seen about eight kilometres further than the oil-light, and that, in time of fog, the range of the former light was more than double that of the latter.

M. Quinette de Rochemont, ingénieur des ponts et chaussées, published in 1870 a report upon the lighthouses at la Hève. Below are some extracts:—

"The electric light having been installed for six years at la Hève, enough time has elapsed to allow us to form an exact idea of the value of this means of producing light for the lighting of coasts. Sailors take pleasure in recognizing the good services rendered them by the electric light. The advantages of the system have been highly appreciated: the increase in the range of the light is very apparent; and, although, on a slightly foggy weather, many ships can continue their voyage, and enter the port at night, which they could not when oil was used. The light, which at first was rather unsteady, gradually acquired a remarkable fixity, thanks to the improvement of the apparatus and the attention bestowed by the keepers. The fears which were at first entertained regarding the delicacy of certain parts of the apparatus are not realized in practice. The accidents have been rare, the extinctions short and very few,—two only during this period of six years having had a notable duration: one, of an hour, was due to an accident to the steam-engine; the other, of four hours, should, it appears, be attributed to malevolence. Under these circumstances it seems hardly worth while to worry about possible accidents."

Since 1863 experience has only confirmed the favorable views of M. Quinette. The lighthouses of Gris-Nez, France; Cape Lizard, England; Ostenx, Russia; and Port Said, Egypt,—have been provided with electric apparatus; and there is a question of placing it in the lighthouses of Flushe and Palmyre, France, and in several lighthouses in other foreign countries.

The following information was furnished by MM. Sautter and Lemonnier:—

"When the light is to be fixed, the optical part of the apparatus is composed of a lenticular drum of *papier mâché*, which renders the rays horizontal in the vertical plane while allowing them to diverge in the horizontal plane. The dimensions of this drum vary from a diameter of half a metre for a fourth-order light to one metre for a first-order light. This increase in diameter of the apparatus is sensibly proportional to the increase in diameter of the carbon-pencils between which the voltaic arc is produced, and which determine, by their position, the dimensions of the electric light. It follows from this that the vertical divergence remains the same in the different types of apparatus. When the light is to be revolving, the fixed lens is surrounded by a movable drum formed of straight vertical lenses, of which the form varies according to the characteristics desired to be given to the light."

Revolving electric lights have this great advantage over revolving oil-lights: the flashes can be given a duration equal to that of the eclipses. In oil-lights, when the light is concentrated in the form of flashes, there are two ends in view: 1°, to augment the intensity, and consequently the range, of the light; 2°, to create an appearance different from that of a fixed light. The first can only be obtained by giving the flash a duration much shorter than that of the eclipse; or, in other terms, by making the angle of the luminous beam a small part of the angle embraced by the lens. Moreover, this angle depends on the dimensions

THE ELECTRICAL WORLD.

THE ELECTRICAL WORLD

A Weekly Review of Current Progress in the Practical Applications of Electricity.

VOL. II.—No. 1. NEW YORK, SEPTEMBER 1, 1888. $3 PER ANNUM. 5 CENTS A COPY.

The Edison System on Board Steam Vessels.

The Edison system of electric lighting has contributed largely to demonstrate the merits and advantages of the electriclight over all other means of illumination for steam vessels, by the uniform success and satisfaction which have attended its use in numerous installations. Assuredly it needs but an installation like that on board the Pilgrim to prove the general practicability and the desirability of the electric light for steam vessels of all kinds, and at the same time to bring into relief the particular excellence of the Edison system for the purpose.

Although we gave in our issue of June 23 an extended notice of the installation on the Pilgrim, which was a thorough enough review of the peculiar features of this electric lighting feat to call forth from the officials of the

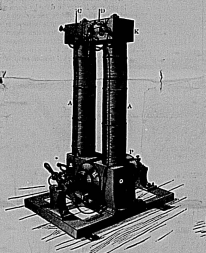

FIG. 1. THE EDISON Z DYNAMO.

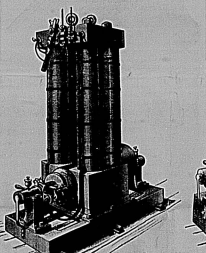

FIG. 2. THE EDISON L DYNAMO.

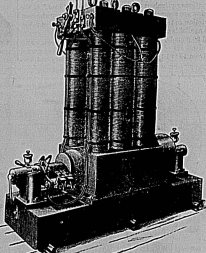

FIG. 3. THE EDISON K DYNAMO.

Edison company the compliment that it was the best account yet published on the subject, and which also enjoyed the distinction of being reproduced in several of our foreign exchanges, we had nevertheless proposed to enlarge still further on the installation, with illustrated descriptions of the apparatus used. Meanwhile, however, installations of the Edison system have been in progress on several other vessels, and the details and data made accessible to us concerning them reveal some novel features of value. In view of the fact that the adaptation of the electric light to navigation is an important question at the present time, and one which is being made the subject of comparative study by electricians as well as shipowners and builders everywhere, we thought that a comprehensive review of all these installations, with illustrations of the principal apparatus used, would afford our readers a better idea of the nature of the problem, and, at the same time, of the adaptability of the Edison system to its requirements. The installations which we shall notice have either been lately completed or are in process of completion, and consist of one ferryboat, one United States man-of-war, and three merchant and passenger steamships. The apparatus used in these installations is the same as was used in the Pilgrim, with some exceptions. We shall, therefore, refer to the Pilgrim plant only casually to point out the differences.

FERRYBOAT FANWOOD.

The installation on board the ferryboat Fanwood, of the Communipaw Ferry line, operated by the Central Railroad of New Jersey, is the first we shall describe. The plant comprises 60 lights operated by one dynamo-electric machine of the type known as "Z" (Fig. 1), placed in the hold of the Fanwood. It is, of course, impossible to do full justice to the Edison machines in the limited space allowed by a general description like the present. We shall confine ourselves to a brief glance at their most salient features. The "Z" machine consists of a tall, upright U magnet, in the magnetic field of which revolves a cylindrical armature. The pole pieces rest on the iron base of the machine, a solid piece of non-magnetic material being interposed so as to prevent the short circuiting of the lines of force between the two pole pieces by the iron of the base. The cores of the armature coils are built up of thin sheets of iron insulated from each other by paper discs and strung together on a wooden mandrel, through which passes the shaft. By thus constructing his cores of isolated pieces, Mr. Edison obviates in a great measure the occurrences of Foucault currents, and to this is due the comparative absence of heat in the armature, even after it has been running several hours. The armature, which is ten inches in diameter, is wound in 54 sections that loop between the commutator segments, as in Alteneck armatures, but the "diagram" of winding is different, and is of Mr. Edison's invention. An excellent feature in the construction of these armatures is the covering of stout canvas, which fits over the ends closely. This not only protects the connections from accident, but prevents the churning of the air, which is noticeable in uncovered armatures, and which is undoubtedly accountable for the absorption of some mechanical energy without useful return. Mr. Edison adopted a different course also in disposing both the commutator and the pulley (P) inside of the bearings. We have no doubt that the arrangement presents advantages over the other way of placing the commutator and pulley outside of the bearings. The conductors from the collecting brushes lead up to insulated binding posts *C D* above. One of them includes a hand switch, by turning which the circuit may be opened or closed.

The dynamo is worked by means of an Armington & Sims high-speed engine of a type specially designed for electric light purposes, and shown in Fig. 4. This engine is of the class designated "B" by the makers, and has a cylinder 8½ × 10 inches.

These engines are remarkably small and compact in design, weighing about 4,000 lbs., and occupying a floor space of only 48 × 90 inches. The engine is characterized throughout by excellent adaptation of parts and skillful workmanship, an excellent proof of which is the fact that when running at the speed of 300 revolutions, as in this case, it can scarcely be heard. The chief feature of excellence of these engines, however, and that which probably determined their adoption by the Edison company, is the precision with which the governor performs its functions. The principle on which these engines are

built for the Oceanic Steamship Company and which will ply between San Francisco and the Sandwich Islands, have both been fitted with identical installations of the Edison system. The installation consists in each case of 226 lights, for which the current is supplied by two "Z" and one "J" dynamo-electric machines, operated by a "B" Armington & Sims engine, making 300 revolutions per minute. The automatic regulator is not used, the variations of current being so slight that a hand regulator answers all practical purposes. The lamps are of the "A" type of 10 candle power and give 16 candles. They are divided as follows:

Dining Saloon	12
Passengers' cabins	100
Staterooms	100
Social Hall	1
Ladies' room and bath-room	2
Directors' room	2
Smoking room	1
Music	1
Doctor	1
Engineer's, steward's, purser's rooms, barber-shop	3
Kitchen	3
Hall alley	1
Engine-room	10
Boiler-room	4
Boiler-room	4
Steerage	16
Hunting and mooring engines, etc.	20

THE EDISON DYNAMO-ELECTRIC MACHINES.

governed is, besides, very simple indeed. It consists in regulating the throw of the slide valve by causing the eccentric moving it to vary in eccentricity. This is done by using two eccentrics. One is fastened to the crankshaft as usual. The other can move on the first, and the slide-valve is worked by the eccentricity of its periphery

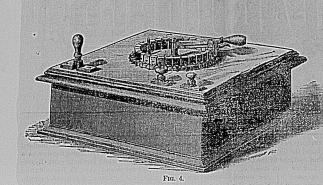

FIG. 4.

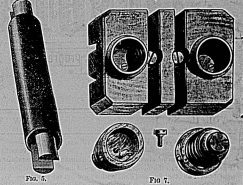

FIG. 5.

FIG. 7.

just as if it were directly attached to the shaft. It is movable, however, and under the control of the centrifugal force of two weighted levers carried by the fly-wheel, by which it can be caused to move around. Now, when the speed is below the normal rate to which the engine is adjusted, the outside eccentric moves over the inner eccentric, so as to produce a greater total eccentricity, and the throw of the slide-valve is consequently lengthened. On the other hand, the moment the speed exceeds its normal rate, the second eccentric rotates and the total eccentricity is diminished so that the throw of the valve is shortened.

This governor is said to be so quick and accurate that variations equivalent to nearly the whole "load" of the engine are compensated for instantly, so that not the least variation in the light can be perceived. The steam pressure available on the Fauwood is low, varying between 12 and 20 pounds, so that a condenser has to be used. This condenser is of the Knowles pattern and affords a vacuum of from 10 to 13 pounds, ten water of the ordinary temperature being used for condensing. This makes a total available working pressure ranging between 20 and 30 pounds.

The engine is belted direct to the dynamo, the driving pulley being 40 inches in diameter, and the dynamo is driven by a 10-inch pulley at its normal speed of 1,500 revolutions. The electromotive force developed is controlled by the amount of resistance in the field magnet circuit of the machine. In this case the electromotive force is maintained at a standard of nearly 100 volts, and the current supplied to the external circuit has a volume of about 50 amperes. The current is taken from the terminals of the machine by conductors of No. 8 insulated copper wire, laid in grooved moldings. This size of wire, which has an area of section of 16,510 circular mils, is considered sufficient to carry the current with safety. In the Pilgrim installation, however, it will be remembered, the conductors have a smaller section, and are both inclosed in an iron pipe filled with an insulating compound, as shown in Fig. 5, which represents a short section of such a conductor. The area of section of the Pilgrim is nearly 500,000 circular mils.

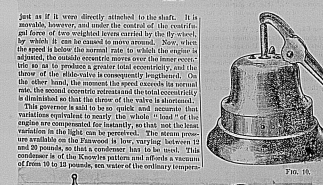

FIG. 10.

FIG. 12.

FIG. 6.

FIG. 8.

FIG. 9.

which supply the lamps there. The general distribution above is effected from the "centre of illumination" as on the Pilgrim, and all similar installations of the Edison system. The main lead divides into two branches which pass up to the middle house, one on each side, to a small "switch closet" situated above the roof of the shaft on either wall. At this point the conductor divides into five branches. Each branch is provided with a safety-catch and also with a special switch. Thus, if an accident happen on any one of the five branches the safety catch will automatically cut the circuit at this point or if in any case it becomes desirable to interrupt the current purposely in one part it may be done by means of the switch. Moreover as all the switches are collected together and conveniently located, the whole system is under the easy control of the engineer. The switch closet can be locked and thus all possibilities of willful or ignorant tampering are avoided. The safety catch, shown in Fig. 6, is an ingenious device by means of which a fusible strip is

FIG. 13.

be conveyed this form of conductor—which is made of varying sizes—is always used, being preferable for many reasons; but when a comparatively small volume of current only is to be carried ordinary copper wire is used.

The mains from the dynamo proceed two to a bunches, which extend the whole length of the hold, one on each side, and

FIG. 7.

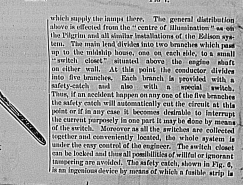

FIG. 10.

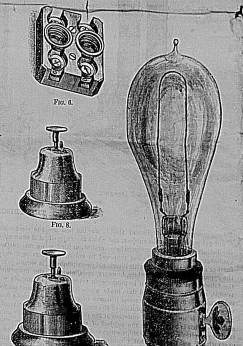

FIG. 1.

FIG. 11.

FIG. 14.

FIG. 6.

FIG. 8.

FIG. 9.

included in each conductor. The general arrangement of the Edison safety catch will be plainly seen from the figure. The screws serve to insure good contact with the conducting wires. The central cavity is lined with thin sheet brass, which is provided with a screw-thread into which a cap can be screwed. This brass thimble is connected with one of the strips of metal through which the connecting screws pass. At the bottom of the central cavity is a disc of thin brass which is connected with the strip leading to the other connecting screw. Now a short piece of fusible wire is soldered to this disc at one end and to the brass thimble at the other, thus completing the electrical connection. It will be seen that each side of the safety catch is independent of the other. Only one side may be used if desired, the other conductor being permitted to run undisturbed by cutting out, but this makes "assurance doubly sure," and is equivalent, in fact, to two safety catches on.

When the heat developed on that branch of the circuit becomes raised abnormally one of the two, or both, fusible strips will be fused, and thus open the circuit. An interesting and ingenious modification of this safety catch used on the Pilgrim and other boats may be conveniently described here (Fig. 7).

This form is intended for use at the points where two conductors are tapped by branches. It supplies at the same time an easy and convenient manner of effecting the connection between the mains and the branches at the point of division or bifurcation. It will be seen that there are two double grooves in this case. The two vertical grooves in front receive one set of conductors and the two horizontal grooves (on the reverse side) the other set, the screws serving to secure them and at the same time to convey the current to the brass lining of the cavity with which they are in electrical connection. In this case it is not necessary to cut the main wires. From the bottom of each cavity extend metallic strip to one of the horizontal screws serving to fasten the branch at the same time to provide electrical connection between the sides and bottom of the cavity is effected in this case by a kind of screw that contains the fusible strip and which is represented separately at the lower part of the figure.

The cap screws into the cavity. To the inner surface of its metallic covering one end of the fusible wire is soldered, as seen in the left hand view; the other end being soldered to a brass disc on the tip of the cap which touches the metallic strip at the bottom of the cavity when the cap is screwed down firmly, thus completing the electrical connection between the main and the branches. When the strips become fused, the caps are taken out and sent to the factory or to be repaired, and other caps may be put

FIG. 12.

FIG. 6.

FIG. 8.

FIG. 9.

the bottom of the central cavity is a disc of thin brass which is connected with the strip leading to the other connecting screw. Now a short piece of fusible wire is soldered to this disc at one end and to the brass thimble at the other, thus completing the electrical connection. It will be seen that each side of the safety catch is independent of the other. Only one side may be used if desired, the other conductor being permitted to run undisturbed by cutting out, but this makes "assurance doubly sure," and is equivalent, in fact, to two safety catches on.

When the heat developed on that branch of the circuit becomes raised abnormally one of the two, or both, fusible strips will be fused, and thus open the circuit.

An interesting and ingenious modification of this safety catch used on the Pilgrim and other boats may be conveniently described here (Fig. 7).

This form is intended for use at the points where two conductors are tapped by branches. It supplies at the same time an easy and convenient manner of effecting the connection between the mains and the branches at the point of division or bifurcation. It will be seen that there are two double grooves in this case. The two vertical grooves in front receive one set of conductors and the two horizontal grooves (on the reverse side) the other set, the screws serving to secure them and at the same time to convey the current to the brass lining of the cavity with which they are in electrical connection. In this case it is not necessary to cut the main wires. From the bottom of each cavity extend metallic strip to one of the horizontal screws serving to fasten the branch at the same time to provide electrical connection between the sides and bottom of the cavity is effected in this case by a kind of screw that contains the fusible strip and which is represented separately at the lower part of the figure.

The cap screws into the cavity. To the inner surface of its metallic covering one end of the fusible wire is soldered, as seen in the left hand view; the other end being soldered to a brass disc on the tip of the cap which touches the metallic strip at the bottom of the cavity when the cap is screwed down firmly, thus completing the electrical connection between the main and the branches. When the strips become fused, the caps are taken out and sent to the factory or to be repaired, and other caps may be put

FIG. 13.

FIG. 1.

FIG. 11.

FIG. 14.

in their place. The switches used also constitute a most interesting device (Fig. 8). In order to give the reader an idea of its construction, we will refer to a larger size (Fig. 9), which is used on the Pilgrim and other boats, and which is shown with its brass covering partly removed. The two ends of the conductor are screwed to two pieces of metal *A* *B* by means of large, flat-headed screws. From each of these two pieces of metal, which are insulated from each other, two contact springs *a* *a* *b* *b* project upward vertically. By depressing the knob or handle, in opposition to the spiral springs shown in the figure, the flat contact strip of copper *C* screwed in a block of insulating material, is lowered down so as to form electrical communication between the springs *a* and *b*, closing the circuit. As the rod *O* is lowered, moreover,

FIG. 7.

FIG. 10.

FIG. 1.

FIG. 11.

FIG. 14.

FIG. 6.

FIG. 8.

FIG. 9.

a catch is forced by a spring into the notch in the rod *O*, shown in the figure, and thus the switch is locked in the closed position.

The catch holding the rod *O* is controlled by a detent or trigger *N*. Therefore in order to open the switch it is only necessary to move this detent slightly. The moment the catch leaves the notch in the rod *O* the spiral springs force the switch up with a jump, thus breaking the contact between *a* and *C* instantly. This rapid motion on breaking the circuit is of great importance, and it is for this purpose that the switch has been constructed in this form. When a branch conductor is carrying a current of large volume, say 50 or 75 amperes for instance, the vaporization or deflagration of the metal on rupturing the circuit is likely to cause the formation of an arc, which would still keep the circuit closed, while it would give rise to some danger. If, however, the rupture of the circuit is made very abrupt the arc doesn not have time to form.

The same design is used in different sizes. Thus, in some cases where the switch is intended to be adapted to a large main, the springs are so powerful that the rod has to be depressed by means of a lever, as shown in Fig. 10. On the other hand, the switch is used in smaller size for small branch conductors and for single lights (Figs. 11, 12).

From the "switch closets" on the Fauwood, the five branches run upward and across the ceiling of the midship house on each side, where they divide into two sets, three branches going toward one end of the boat and two branches going the other way. Each branch supplies one of the chandeliers in the cabins, there being three chandeliers at one end of each cabin and two at the other, owing to the fact that the cabins are longer at one end of the boat than at the other.

The sixty lights are divided as follows:

Cabins, each 3 chandeliers of four lights	40
Middle house, engine room, 2 four-light chandeliers	8
Midship deck	4
Two houses, 1 over each	2
Bow	10
	60

The conductors supplying the current to the lights in front of the midship house at each end, and the branch which supplies the light over each pilot-house, first go to the pilot-house itself and pass through switches by which the three lights may be controlled, so that if the light they cast forward interferes with the pilot's vision in a dark night, they may be put out temporarily.

The lamps (Figs. 13 and 14) are of the well-known Edison make, with elongated glass bulbs and carbon filaments in the form of a U. As seen in Fig. 13, the joint between the lamp and its fixture is made in the same manner as in the double safety catch, having a screw cap (Fig. 7). The circular wall of the cavity of the fixture in which the lamp is screwed are connected with one wire and the bottom, which is insulated from it with other. Likewise the metallic disc on the tip of the lamp base is connected with one end of the carbon loop and the threaded portion with the other. Therefore this simple operation of screwing the lamp into the fixture suffices to form the connections. The design of the chandeliers is very unique and tasty. The installation is now complete, and the Fauwood began in resume its regular work a couple of days ago. It is scarcely necessary to add that the lights work well and give entire satisfaction. One feature on which we may take occasion to compliment those intrusted with the work is the particular care which was taken to conceal the wires. All what have been beautifully arranged in all suggestions of wiring. All what have been beautifully arranged in all suggestions of wiring. All what have been beautifully arranged in all suggestions of wiring

THE GRAMME DECISION.

Of the decision rendered by Judge Blatchford this week, in the suit of the Gramme Electrical Company against the Brush, Croxton & Hochhausen Electrical Company, for infringement of the Gramme patent, it may be said that it has surprised many by the quick appearance, while it has surprised many more still by the manner in which it disposes of the case. That the verdict would be rendered in favor of the Gramme Electrical Company was generally anticipated and expected, even by many who had occasion to hope for a different decision. Under the circumstances, a decision adverse to the Gramme Electrical Company must have seemed a decidedly agreeable surprise indeed. Those whose conscience had made them realize that they were trespassing—consciously or unconsciously, as the case may be—upon the rights of others, have undoubtedly felt relieved by the decision, while those who have been conducting their business in accordance with the belief that they were not trespassing upon the rights of others, have undoubtedly felt relieved by the decision, for the reason that it has put an end to the uncertainty which has existed in their minds as to the validity of the Gramme patent, and has thus relieved them of the fear of being compelled to pay royalties to the Gramme Company. The decision is, therefore, a relief to both parties, and is, consequently, a satisfactory one to both parties. It is a decision which will be received with satisfaction by the public at large, because it will put an end to the uncertainty which has existed as to the validity of the Gramme patent, and will thus relieve the public from the fear that the Gramme Company would, at some future time, attempt to collect royalties from those who have been using Gramme machines. It is a decision which will be received with satisfaction by the Gramme Company, because it will relieve that company from the necessity of bringing suits against infringers, and will thus relieve it from the expense of such suits. It is a decision which will be received with satisfaction by the defendants in the suit, because it will relieve them from the fear of suits, and from the expense of defending suits. It is a decision which will be received with satisfaction by the public, because it will relieve the public from the fear that it will be compelled to pay royalties to the Gramme Company. It is a decision which will be received with satisfaction by all parties, because it will relieve all parties from the fear of litigation, and from the expense of litigation

ELECTRIC LIGHTING MEMORANDA.

The principal topics of the week in electric lighting circles—or perhaps it would be more accurate to say circle—has been the report of the Committee of Inquiry upon the affairs of the Metropolitan Brush Company. It may be remembered that the last general meeting of the proprietors of the Company was of the usual character—that is to say, tempestuous. The Directors were vilified, the accounts rejected, and a Committee of Inquiry (nominated from the discontented shareholders) appointed duly of investigating the previous conduct of the Company's affairs. The report was couched in the strongest language, with reference to the floating and management of the concern; and the Committee concluded their labours by filing a petition for winding up the Company. The principal reason for continued existence proffered by the Directors at the general meeting was that the Company had secured a Provisional Order for lighting a portion of Holborn, and they hoped to carry it out at a profit. The Investigation Committee have satisfied themselves that the Order can only be carried out at a loss; and, moreover, that as, to comply with the conditions of the Order, the Brush Company (the licencee for using which cost the Company £295,000) cannot be used alone, the Company would have to begin operations by acquiring rights to employ other apparatus. The Directors met the issue of this alarming statement by distributing another circular, simply denying the assumptions and conclusions of the Committee, but without attempting to disprove them by arguments. The Board contented merely that in filing the winding-up petition the Committee exceeded their powers. Meanwhile, the Chairman, three other Directors, and the Solicitor to the Company have resigned their offices. The last rumour in connection with this affair, which has attended the notice of several daily newspapers, is to the effect that the discontented shareholders have been "squared," and that peace reigns once more at No. 110, Cannon Street.

The report and statement of accounts of the Anglo-American Brush Company—the "old original" grandfather of all the Brushes in the eastern hemisphere—has been issued, and is a most remarkable document, much too complex for thorough examination within the limits at our disposal in this column. It is exceedingly difficult to understand the precise significance of accounts of this order, which assumes a general tendency to writing off is manifested in various places. The Directors confess to a "heavy loss;" but the portion of the Company's transactions, their dealings with Mr. Lane-Fox, in respect of his celebrated patents, may be studied. First, Mr. Lane-Fox sold his patents to the Company; then he agreed to buy them back again for the sum of £20,000. Then he would not effect "a resale, upon the result of which he counted, to enable him to settle the claim of the Corporation." So the "Corporation" kept £14,000, which they owed to Mr. Lane-Fox as part payment. Then the lawyers went to work; cross-suits being instituted respecting those monies and counter-claims. Then a compromise was effected, whereby Mr. Lane-Fox got back his patents, and granted a license for their use to the "Corporation." He also agreed to pay the "Corporation" 20 per cent. of all the profits that he might make on these. All this, and for the first charge upon all Mr. Lane-Fox's electrical patents, "the Corporation agreed to transfer to Mr. Lane-Fox £14,000 in shares of the International Electric Company, and to make him a cash advance." Was ever such a jumble of buying and selling? Who could tell from all this who—and who—was bought and sold? Nay, everybody who owes £60,000 which he cannot pay gets off with a jumble of shares, a cash advance, and apparently the same

The oldest Electric Lighting Company in England—or rather, to be more strictly accurate, the oldest system that has been longest in operation—is the Jablochkoff; perhaps best system of arc lighting for street lamps is not a guarantee of financial prosperity; and, after experiencing much trouble, the present Company is to be wound up very shortly. It is intended to form another Company, to take over the property and business of the one that has failed. The existing holders of paid-up shares will receive ordinary shares of the new venture, which rank behind twice their number and value in 6 per cent. preference shares. If a sufficiency of the latter class of shares is not subscribed for, it is difficult to see how the concern can go on.

The annual meeting of the Electric Sun Lamp and Power Company has lately been held, when the Directors, with Lord Henbourne at their head, resigned in a body, and a new Board was appointed. This change has been explained as being due to the necessity for reorganization on a more practical and economical basis; the fashionable advertisement element having been proved incapable of doing business. When executing the "happy despatch," the noble Chairman laid the usual fling at the Board of Trade for opposing in the bad the aspirations of the Company. Some opinion that it would be better to wind up the concern voluntarily, without further delay. But this course was opposed; and therefore the Company will probably be allowed to drag on its languid existence until all the capital has been spent. The Chairman gave the comforting assurance that even if the Company went into liquidation, the unpaid capital would be called up. Under these conditions, the new Directors, who were described as holders of half the capital began their reign with free powers to do what they like with the money lists.

ELECTRIC LIGHTING MEMORANDA.

The accounts of the Swan Electric Light Company, and the proceedings at the extraordinary general meeting of the Company on the 15th inst., do not give the circumstances of the concern in a very favourable light. The capital received amounts to £210,125, against which stands a sum of £219,407 paid for British and Foreign patents, and another sum of £51,608 for plant and stock-in-trade. The profit and loss account admits a loss of £903, which, with £5000 for preliminary expenses, makes an unfavourable balance of £5903. On June 30 the cash in hand was £16,532, and debts receivable amounted to £20,551, while the liabilities were £35,786. So that, assuming the debtors to be solvent, and the debts to be paid in full, the available liquid assets were just over £20,000, which, for a concern constructed upon a capital expenditure of nearly £200,000, can scarcely be called a strong position, especially as the business is worked at a loss. At the extraordinary general meeting, the Chairman said he believed the Company had made a profit of £7000 clear of all expenses; but as this has been written off for depreciation, the shareholders must wait awhile for their dividend. The meeting was called to approve of the Bill in Parliament for enabling the united Swan and Edison Companies to undertake the Provisional Orders obtained by the two Companies separately; but it was stated from the chair that all difficulties had been removed, and it was hoped the desired object would be attained "without so expensive a "process as an Act of Parliament." From this it may be understood that the Bill will be dropped; though whether or not the Orders will be carried out any the sooner remains to be seen.

From some recent proceedings in the Chancery Division of the High Court of Justice, it would appear that the process of cutting up a defunct Electric Lighting Company may sometimes be nearly as costly and troublesome as the operations of the Company while living. A concern rejoicing in the name of the Electric Carbon Storage and Apparatus Manufacturing Company of Scotland, Limited—registered in England as an English Company, but having its manufactory situated at Leith, near Edinburgh—has come to the usual end. The Company tried to do business in England from its Scotch home, and on one particular occasion distinguished itself by endeavouring to start an installation of electric lighting in an important parish of South London, whereof the governing authorities at the time manifested a desire to dabble in this kind of speculation. The attempt failed, however; for the promises of the Anglo-Scottish speculators were too conspicuously hollow; and shortly afterwards the Vestry of whom they were addressed received from the alarmed ratepayers a sharp check in their exchequer. Little was heard of the Company with the long name; but it now appears that their property in Scotland has gone under the auctioneer's hammer. The auctioneer has wisely held possession of the premises at the request of his own charges, and also because certain processes known in Scotch legal practice have been served on him, forbidding him to part with the rest of the money. The English liquidator has now interfered, with the object of having the money paid into Court; but the auctioneer objected that if he obeyed any such order of an English Court he should be disobeying the injunction of the Scotch Court. Eventually, the liquidator obtained his point, coupled with the obligation to take steps for harmonizing the orders of the two national systems of jurisprudence. All this is very interesting for the lawyers concerned on both sides of the Tweed; but the creditors and shareholders of the Company must regard these complicated proceedings in a different light.

The poor Metropolitan Brush Electric Light and Power Company must be in desperate straits—or, indeed, is a notorious fact—when one of their officials is driven to write to a newspaper published in Liverpool, complaining of the recklessness of the Committee of Shareholders who are determined to wind up the Company. This gentleman calls himself "the Alien Master of electric lighting on a large scale in this country"—whatever this may mean. It is certainly the city where the first considerable disaster overtook the Brush system; but this is scarcely a pleasant reflection for anybody connected with the speculation. The burden of the official complaint is that the Metropolitan shareholders are blind to the extraordinary advantages of the Provisional Order for Holborn, which the Directors and officials desire to carry out, in the spirit—almost acknowledged on their part—of throwing good money after bad. Why the pitiful story should be told to a Liverpool multitude, or what possible effect the favourable judgment of Liverpool people could have in respect of a Metropolitan electric lighting speculation, is not apparent. The tone of the communication in question is despondent in the extreme, and not very welcome in warrens. There is a poor look-out, undoubtedly, for the later and less fortunate school of electricians and other officials who are now trying their hardest to keep the Brush bubble inflated; but, again, what has Liverpool to do with the fortunes of the London concern?

American Gas Light Journal. March 17, 1884.

THE ELECTRIC LIGHT IN PHILADELPHIA, PA.

Again is the house of the electricians divided against itself. This time it is a fight for monopoly. The Electric Lighting Company, which is virtually the Brush Electric Light Company, has filed a bill in the courts here praying that the Underground Electric Light and Power Company be enjoined from supplying light in this city by means of electricity, and asking compensation for damage done to their business by the said Underground Company. The Brush Company says that its right to supply light by means of electricity is, by the terms of its charter, exclusive, "until the said corporation shall have, from its earnings, realized and divided among its stockholders, during five years, a dividend equal to 8 per cent. per annum on its capital stock." Such a dividend, it is asserted, has not been paid; and therefore the Underground Company is a "pirate."

About three years ago the Brush Company built an extensive and well appointed plant in the neighborhood of Twentieth and Chestnut streets; and, if memory serves aright, first illuminated our streets on the 5th day of December, 1881. For one year they ran their plant on Chestnut street, from river to river, gratuitously. Then they succeeded in making a contract with the city, and now furnish us with 66 arc lights along our streets, for which we pay 55 cents per night per light. They illuminate Chestnut street, from the Delaware to the Schuylkill, and then crossed across the bridge to Thirty-third street; and Market street, from Thirty-third street to Forty-first street, in West Philadelphia.

The city, however, takes a very small proportion of their business. They have now 636 arc lights in operation for private consumers, and contracts out for some 50 more. Their plant is running to its full capacity to supply that demand, and they are obliged to put off new customers until they are able to put up new dynamos. To private parties the charge for lights is from $22 to $28 per light per month, according to the number of lights; that is from about 73 cents to about 93 cents per night.

Now an outsider might suppose that amount of business was all that the Brush men could desire, and that they should grow rapidly rich, if the stories of the economical production of electricity be true. But that statement about the eight per cent. dividend belies such seeming prosperity, and shows us that there must be something radically wrong somewhere. A partial explanation is that here, as elsewhere, they have had to buy their experience very dearly; their works were, in a measure, experimental, and they were handling something the exact nature of which is not quite known, and which is prone to freaks that are often as costly as they are curious.

And then, about three months ago, a cloud appeared upon the horizon. The Underground Electric Light and Power Company obtained from the City Councils permission to use, for the purposes of experiment, the old iron lamp-posts along Chestnut street that had previously been used for gas lights, which, when the electric illumination became satisfactorily established, were no longer lighted. They then placed two of their dynamos in the new *Record* building, and carried their wires thence along Chestnut street, from Ninth to Broad street, through the underground conduits of the American Sectional Company, which are laid at a depth of about two feet below the surface. At each lamp-post they made connections, and took their wires up through the hollow socket. Then they removed the old gas lanterns, and placed in their stead quite handsome "Excelsior" lamps of the Hochhausen pattern, which are in general appearance quite like the Brush. They have run those lights thus far also without expense to the city, in order to demonstrate the practicability of carrying electric wires underground.

So far as it is possible to judge now, they have entirely succeeded. Their lights burn steadily and pleasantly; the intensity of the arc, at such a small elevation, is overcome by using shades that are wholly ground glass—those in the higher lights of the old plant being half clear and half ground glass. In the conduits, opposite each store or dwelling, arrangements are made for connections, and they are now running some lamps for private consumers. Some of these are on side streets, and working very successfully, thus demonstrating the practicability of taking the wires also around corners underground as well as if operating on straight lines. The company is at present busily engaged in fitting up a plant on Eleventh street, near Shissom; and, so far from appearing alarmed at the suit brought against them, are arranging their affairs with the air of men who have come to stay.

Now, whatever be the justice of the pleas of the Brush Company, the public will be sorry to see the Underground Company enjoined from pushing their system here. The good citizens have long protested against the countless telegraph and telephone poles and wires that are strung through our streets, only to be greeted with an additional forest of electric light plant. If such be allowed to continue, it is but a question of time when the very vault of the heavens will be hidden from sight on our principal streets. O, thrice blessed that we are! We have now three aerial systems of electric light operating in our beleaguered city, and they have not yet run their course.

The Brush Company, besides the arcs named before, are preparing to light Delaware avenue, from Vine to South street. The Maxim Company, who had some 25 lights stretched along on North and South Delaware avenue, have just started some dozen lights on Broad street, immediately north and south of the new public buildings, and have strung them on most unsightly wooden poles, that have not even the saw virtues of being straight. And, lastly, the Thomson-Houston Electric Light Company are running their lamps, by sufferance, along the line of the Reading Railroad on Pennsylvania avenue.

Leaving the esthetic consideration out of view, it seems the height of folly to carry through our streets so many wires charged with currents of the highest intensity—nothing less than bottled death and destruction. It has been shown that it is not a necessity so to do, and if we must have the electric light, let us have it under proper conditions. There is no doubt that the overhead wires "must go;" and the sooner the better.

As was shown, the Brush Company is not doing an extraordinarily profitable business, and it is the best conditioned electric light company here. We believe that want of capital hampers the electric men in many directions. The public have ceased to regard the light as a luxury; in fact, it is now almost a synonym for "will-cost" investment. And since electricity has not proved so wonderfully cheap and lucrative as an illuminant, we may soon hear of gas again in street lighting.

And, in that connection, it is curious how little is known, even by well informed people, as to what can be done by gas. They think that its limit is in the burners of the street lamps that they see emulating tallow dips along our highways. Would that the trustees of our gas works here had enterprise and "push" enough to induce the city to give gas a "show" alongside the electric light, and to put up in our streets a few of the new high-power gas lanterns. We warrant that ninety-nine hundredths of the natives would be thoroughly and genuinely astonished. We believe it was done with that result in enterprising St. Louis, Mo., and that it would be anywhere a most remunerative experiment.

Let us hope that gas men will come to the front and "show their hands" before the streets are monopolized by electricity.

A.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [Feb. 12, 1884.

ELECTRIC LIGHTING MEMORANDA.

The truce between the Shareholders' Committee of Investigation and the Board of Directors of the Metropolitan Brush Company, mentioned last week, was of very short duration. After the report of the Committee had been issued, and they had filed their petition for winding-up the Company, numerous interviews and conferences took place between the Committee and the Board, resulting in the agreement of the latter —or the remainder of them badly, for the Chairman and three others had resigned—with the proceedings of the former. This was the foundation for the rumour of conciliation before mentioned. It is, however, the details of the policy adopted by the Committee were subsequently disclosed to the Directors, the latter resumed their hostile attitude, because it transpired that the Shareholders' Committee were determined to have a majority of their number on the Joint Committee to be formed to supervise the winding up. In addition to this, the Shareholders' Committee introduced many things into their programme to which the Board would not consent when they learned the particulars. The hostilities have been actively progressing during the past week; circulars to shareholders and letters to the newspapers succeeding one another without cessation. It has at last been agreed on all sides that this course of action does not settle anything; and so an extraordinary general meeting has been convened for to-day. At this meeting will be decided which side is to have the command in the friendly fisticuffings; and the extent of the powers of the joint Liquidation Committee will be defined. It appears tolerably certain that a demand for the return of a large amount of money will be made upon the promoters; but as the Committee will ask for powers of concluding any compromise that would seem to them desirable, the affair may be brushed up after all. An attempt is to be made to form out the Company's Provisional Orders to Sub-Companies; but this design is almost assuredly proved abortive, either on account of inability to float the Companies for this purpose, or by the action of the Board of Trade, who will certainly look very closely into any schemes of this origin and character.

The Anglo-American Brush Corporation have held their meeting, and passed the remarkable report and statement of accounts mentioned last week. From the report of the proceedings there does not appear to have been any discussion of the figures; so that it may be inferred that the shareholders are resigned to see their property drifting no man knows whither. Of course there was the inevitable laudation of the wonderful 2000-candle Brush lamps, which are so much better in every possible way than any other lamps that can, might, or would ever be thought upon earth. Mr. Hammond was there to talk about the success achieved at Chesterfield, Brighton, and Eastbourne. It may not be uninteresting to remark, with reference to the Brush lighting in the City of London—the only example wherein extinctions are considered as serious and worth advertising at any cost—that a correspondent in a daily newspaper has stated that "between "six and seven" attendants are required to watch the lines of 30 lamps apiece over the length of nearly a mile. This "is about one man every five lamps, each man receiving "at least 47*l.* per annum—a very fair estimate, considering "the character of the duties—each lamp therefore costs, on "this head alone, 47*l.* per annum." Nothing of this was heard at the meeting; but neither was it contradicted. There is small wonder, in such circumstances, to say nothing of the graver troubles of the "Corporation," that even the Directors confess to a heavy loss on their last year's working.

A little more than a year ago Mr. Odevaine R. Coope wrote to *The Times* to say he had lighted his country house at Bere-church with incandescent lamps; and he then gave some figures relating to the cost of the very fine establishment of the system, was £1400 or., and the estimated average expense of lighting 200 lamps for 1150 hours per annum was £292 15*s.* 1*d.*, or after the rate of 0·07 of a farthing per lamp per hour. Mr. Coope has now written again, after a year's experience, to say that beyond a few minutes' troubles caused by the belt slipping, and a little temporary annoyance caused by a drunken engine-driver, he has not had any mishap for the 1823 hours during which the lamps have been in operation. The total cost works out to £359 18*s.* 9*d.*, or, as Mr. Coope says, 0·05 of a farthing per lamp per hour. It may be remembered that when Mr. Coope began his experiment, somebody asked whether all the machinery would not have to be in action to enable a single light to be used in the house; and to this Mr. Coope failed to give a satisfactory answer. Now, also, even *Engineering* asks how it is that all Mr. Coope's lamps were burning, on an average, for hours a day all the year round. Our contemporary says "the inference to be drawn from his "letter is that every lamp was put in action at dusk, and "kept alight until nearly midnight, in all the rooms; as "was absolutely within it, until the engine was stopped for "the night." Of course, this makes the method of computing the cost per lamp-hour appear favourable to the system. "A "farthing per lamp-hour looks a very small sum; but £359 "per year for lighting a single country house is an amount "not very often paid," in the opinion of *Engineering*. Another journal, the *Engineer*, comments on the letter—the author of which, by the way, it persistently calls Coope, as though the writer had never heard of the great brewing firm—and points out that the owner of Hurstbourne Hall has given only the barest cost, without allowing for profits, the cost of long conducting cables, or many other expenses that would heighten the rate at which the same lighting could be supplied by a trading Company. It is undoubtedly the best way to look at these figures in the manner of *Engineering*, and to take note of Mr. Coope's gross expenses, while reserving judgment as to whether his method of reduction to lamp-hours is justifiable.

Electric Lighting at the Bank of England.—In

the course of last year the directors of the Bank of England, who adopting electric lighting throughout the building, resolved as a first step to entrust the Electrical Power Storage Company the fitting up with incandescent lamps of the private dining suite, the bill office, and a portion of the accountants' room, giving a total of 150 lamps. The work has now been completed, and on Monday afternoon the deputy-governor (Mr. J. P. Currie), accompanied by several of the directors, made an inspection of it, and expressed their satisfaction with the result. The Faure-Sellon-Volckmar accumulators spoken of have been adopted. A dynamo charges the 150 lamps at all hours during their ordinary service, or in case of fog or other unforeseen circumstances, to give a whole day's lighting without working it. Swan lamps are used, which are fixed on specially-designed brackets attached to the present gas fittings, each lamp having a switch attached to the present gas fittings, tap, so that the control over the lighting is as complete as under the old system, with the advantage that when desired the whole may be lit or extinguished in a second.

AN IMPORTANT INVENTION!

Now Ready, Price 1*s.*

Directions for Incandescent Lighting.

Being the Latest Information on Electric—Incandescent Lamps on Long Circuits—Combination with Present System—Apparent Gain.

Reprinted for THE STANDARD COMMERCIAL BULLETIN

An Invention which will be welcomed by electric lighting interests everywhere as marking such an important practicability as incandescent light, has just been perfected by Mr. W. S. Stevens, electrician of the New England Westinghouse Electric Lighting Company of this city.

Heretofore incandescent lighting companies have sought for the most part to establish isolated plants. It is only within a few months that the

VILLAGE PLANT SYSTEM

has been considered a success and while there are quite a number of such plants projected and for which plans and contracts have been made, there are but two or three in actual operation in the country. The first one was installed at Roselle, New Jersey, and was installed by the Edison Company, which, by the way, it persistently calls Coope, as though the writer had never heard of the great brewing firm—and points out that the owner of Hurstbourne Hall has given only the barest cost, without allowing for profits, the cost of long conducting cables, or many other expenses that would heighten the rate at which the same lighting could be supplied by a trading Company. It is undoubtedly the best way to look at these figures in the manner of *Engineering*, and to take note of Mr. Coope's gross expenses, while reserving judgment as to whether his method of reduction to lamp-hours is justifiable.

SOME NOTES FROM AMERICA.

(FROM OUR OWN CORRESPONDENT.)

New York, Jan. 15, 1884.

In a former letter,* speaking of electric lighting in New York, I stated that upon the comparatively unsuccessful issue of the Brush Company, and also upon the energy given for their introduction, which they paid, had in hand the lighting of the streets by the electric system of Mr. Brush, and therefore his Company were not willing to put out more until they knew what was to be the result of the working of these experiments. While this would be a correct statement as to what had been carried to the point which would warrant their lighting, nevertheless the unwillingness to supply the system was not true between the Brush Company and the Edison Company. Directly after the latter Company had commenced operations they had their hands full, and the two companies could not attend to the wants of their customers. The former struggled of the Brush system, while the latter Company had their hands full with the Edison system, which, as I have before stated, their interests forced for this country control of the Edison lights, which they purpose using in the near future in connection with Mr. Brush's storage batteries for interior lighting. The special system which they pay, lighting of houses, now operates in the better portion of the city, and would have in its effect, *the rationale* being that a large number of batteries, which would be charged by comparatively small power, and these storage stores. They then lights would be sold to consumers at a less price than they would charge for their lighting, nevertheless the perfect steadiness of this Mr. Brush's improvements of the storage battery. I am informed that the Edison Company have now in their stores in this city a large number of lamps with gold plates. It was the announcement of the Brush Company that they would shortly commence the manufacture of their lamps that induced the difference between them and the Edison Company. The representatives of each of these companies have made free use of the public press in the discussion of their respective merits, and as the result we have been treated to a number of letters in which each party claims the superiority of its system. Mr. Bates, President of the Edison Company, seems to be the very perturbed state of mind. He says that the loss of life, owing to the high tension employed by the Company; and as the public will not pause to discriminate between the systems of the two companies they will have to bear part of the unfavourable condemnation. He says he is particularly distressing to the gentlemen who are putting in the Edison system, that the Company have a number of lamps in their stores for the purpose of the Edison to perfect a plan of lighting which shall allow all other things, would be a success. He says that there will be no difficulty to make this clear to the public, as many lives are lost by other systems of electric lighting. One thing is certain, and that is that all the Edison's public have already had ample opportunity of seeing what the system is capable of, and that they will not be likely to have a very serious effect on the fortunes of his Company. Mr. Bates says, Mr. Brush, of the Brush Company, has stated that this new storage system is not to be in the course of safety, and in support of this statement says that the Company have not as yet, but they will only have a location of 40 lights. Still Mr. Bates admits that it is the 2000-volt current to the batteries, and that the 40 lights are to be run by that, and is keeping the best of the Edison Company awake at night. However, the Brush Company are not yet ready to introduce their new scheme, and will not be for some time to come.

The Edison Company, operating in the streets of New York City, have informed their customers that, the price for their lights will be reduced from the first of April next. The rate they are to charge is 25 cents per 1000 cubic feet of gas in New York by 6 dols. 25*c.* and the candle power 25, I do not see that this reduction necessitates figures in that way. Moreover, the New York Companies are not worrying over what is to be the charge of the Edison Company, as they have been selling gas at 2 dols. 50*c.* per 1000 feet, a difference of 3 dols. 75*c.* per 1000 feet. This has been the case since electric light has had its day; that its present position is one of stagnation as far as retrogression; that it has not hurt the gas business in the past, nor is it going to do so in the future.

The Edison Company have secured permission to lay their mains in the streets of this City. They purpose to manufacture "a rare hydrogen" gas for a term, and to charge for it at the rate of 2 dols. 50*c.* per 1000 feet. The Company agree to furnish gas at 1 dol. 50*c.* per 1000 cubic feet for light the street lamps for 12 dols. a year (the present rate is 17 dols. 50*c.*) Should the Company not have the City the street lamps for the first year they pay for it the next year. It is not yet announced what action of the city will be elected from the Edison Company. Mr. Vanderbilt, the President of the concern, who has recently ruled his central interests, is just possible that the Company will not select any section. Should they do so, it will be a great boon to the City, as they would be directly benefited by the reduction in price, because the burden will eventually fall on the consumers. True, the new Company are restricted as to price, and are enjoined against combining with other companies. But after they once get into operation it would doubtless be necessary to repeal these clauses, imposed as they are only by the Gas Commissioner; so that in the long run the consumer would finally be benefited.

Opposition works are likewise being started in other cities. Chicago, as an example, already blessed (?) with a multiplicity of companies, is to have another, which is to make a water gas. It is passing strange that municipal authorities will not learn from past experience that cheap gas is not to be obtained by cheap opposition companies. On the other hand, a different feeling would the gas loving public of the country to-day if in each city there were but one company, and that one under the legislature as to price and purity!

* Jan. 5, 1884.

GLEANINGS AND MISCELLANEA MEMORANDA.

It has been announced that the Maxim-Weston lights in Queen Victoria Street, City, will be removed in consequence of the Company not being able to afford the expense of keeping them going. The Company explain that the cost of this particular advertisement has been practically thrown away; for, as a matter of fact, they have not been able to extend their connection in consequence, and are no better off, from a business point of view, than when the experiment was started. This is what the letter of the Managing Director really means, although it is not to be supposed that he would write to *The Times* in these words. He says his Company will now wait until the Commissioners of Sewers are "in a position to allot off the City in large sections." By this time the Company may find themselves in a somewhat different condition, if all reports are to be credited. It may be conceded freely that the lighting of Queen Victoria Street by the Company has, on the whole, been very good. It would not be overstating the facts to speak of it as the best street lighting by electricity in London; but the cost must have been enormous.

The position and prospects of electric lighting at the present time have been discussed by the *Engineer* in a decidedly depressing style. It is now the fashion for some of the publications which at one time upheld the system in question through their zeal thin, to assume the attitude of the good-natured but candid friend, and expose all its weaknesses. In pursuance of this amiable policy, the *Engineer* tells the electricians that they have missed their grand opportunity. They are informed that "a sixth or seventh gas-works will give more light than all the electrical apparatus in Great Britain put "together." Yet on their present connection, such as it is, electricians have spent, in one way or another, more than two millions of money subscribed by the public. Our contemporary summarises the principal installations of electric lighting now working in London; and declares, when it is all summed up, that "the work done by the electrical engineers is as a drop "in the ocean compared with that done by the gas engineers." The main reasons for this backwardness are given as, in the first place, want of confidence in the light on the part of the public; and, secondly, that it is not only too dear but too troublesome. This is a very fair statement of facts which are possibly unpalatable to many people, but cannot be ignored on that account.

The Electrical World has a very outspoken article upon "expert quackery," which must commend itself to the smarting consciousness of many disappointed stockholders in electrical concerns. Truth to tell, one of the great plagues of the investor are the quack professors—chemists, electricians, and what not, who are always to be found ready, at the beck and call of promoters, to deliver lectures, make speeches, and indite testimonials in favour of money-getting schemes. The public have of late heard enough of the exploits of these gentry, who may occupy chairs of physics and chemistry at educational establishments, but are always to be heard of at meetings of Companies where the shareholders are required to receive instead of dividends. Our contemporary expresses the hope that "simple ventila- "tion will purify the expert business, without a course of "active disinfection." We hope so too; for it is certainly time to see men who should occupy an honourable position—men with the title of "Professor" before and the coveted initials "F.R.S." after their names—in the train of stockmarket speculators.

Mr. Edison has been interviewed on the vexed question of electrical motors for railways, and has stated that he is building a locomotive of this order for the Metropolitan Railway of London. The great inventor declares his belief in the future applicability of such engines for short runs, and where there are many stoppages. We will reserve our own prophecy until the machine in question is regularly running between the Mansion House and the Tower. It must be confessed that the chief peculiarity of most electrical railways so far has been the prolonged use of "temporary" steam locomotives to do the work. An instance of this is supplied at Wimbledon this year, where, as locally announced some months ago, the Gamp tramway was to be worked by electricity. As a matter of fact, the work has been done as of old by the "Wharncliffe" steam-engine; the electricians not being ready in time. We have not discovered any published notice of this fact elsewhere, although, of course, the declaration of what the electricians were going to do was blazoned far and wide.

From Sydney intelligence comes to the effect that the local Edison Electric Light Company—the only system that was regarded there with any degree of favour—are under a cloud. The light was introduced, with the usual flourish, into the offices of the leading newspapers, the Exchange, and a large restaurant. At all those places—the only ones where it was tried—the lighting has now been discontinued, of course without public notification of the fact. Gas in Sydney is 9*s.* per thousand cubic feet; so the Edison system had as good an opening as at home in New York, and much better than in England. The reasons for the discontinuance of the system cannot be ascertained; but the result is naturally a great damper upon the Edison cause in Australia. Yet one would imagine that the conditions for the development of incandescent lighting in the Antipodes are peculiarly favourable. Probably the old drawbacks—costliness and unreliability—are at the bottom of the trouble here as elsewhere.

of supply. At a meeting of the Local Board in September, 1867, Mr. Marshall remarked that without an increase of 50 per cent. in the supply the whole water-seven hours now, then fifty-required—would be deficient. The venerable Archdeacon then went on to refer to the eminent geological and engineering testimony given at the former inquiry in favour of the chalk scheme; and said he ventured to assert that the Local Board had made up their minds that they would not go to another source for water. If this scheme now proposed was sanctioned, the Board would ultimately incur the responsibility of bringing down the water from Ware.

The following is the report presented at the meeting:—

Mr. *Bramley*, C.E. (partner in the firm of Bateman and Co., and Engineer to the Somerset Water Company), said he thought the present source of supply at Ely quite a wrong one, and that filtration, on whatever system, would only elevate the water from its natural condition. There was no ample supply of pure chalk water a few miles off. Had he been called in in the first instance, and shown the samples of water taken from the river, he should have strongly advised the Board to go to the chalk. He had not the slightest doubt that they could get a supply of water from the chalk hills to the east of Ely. A total lodging would cost 250 or 300 for 10 or 20 feet in depth. His opinion was that and filtration would remove particles in suspension, but not those in solution; so that, as far as his opposition was concerned, the water, though clear, might be no better for the process. He believed the town would drink that, when the water was turned, the filters would be too little to receive it up. He thought the expenditure of £2000 in the construction of the filters would be thrown away money. He had seen the supplies which were from very much worse sources found at the entrance of the chalk. He had no fear whatever that there would be any lack of water at any time. In the case of a plant like Ely he would estimate for a consumption of 20 gallons per head daily. His firm had had a good deal of experience in stopping waste. At Stone-land Ely shielding the iron mains and using waste-water meters they had reduced the consumption from something like 40 gallons per head per day. Much of the water wasted by defective fittings. At Ely the defects in the service pipes and fittings might be detected and remedied. For supplying Ely with water from the chalk, he would sink the well at Teddington. He had estimated the population at 9000; not the daily consumption of water, including that for road watering, at 20 gallons per head, or 180,000 gallons in all. There were some scattered villages which would require to be supplied, but the population of Ely was increasing daily, making a total population of 10,000 persons. The water could be pumped, during twelve hours of the day, with a 12-horse power condensing engine; and 1000 gallons would be raised if necessary. He estimated the cost of the works, including pumping station, shifting of well, filtering tanks, engine and boiler, and cottage, at £3000. He estimated that the annual working expenses would be about £300. He would recommend 10-inch cast-iron mains for the town, and 12-inch and 15-inch cast-iron mains, 12,000 yards long, would be required along high road and joined on the present main at Ely. He considered a very large annual saving upon the present expenditure would be effected. He could, in fact, be as considerable as nearly to pay the interest on the loan borrowing the sum of £15,000. He considered that the capabilities of the whole plan for the chalk supply would be less than that of the extreme supply of the Lea and Ware. He had seen a great many wells sunk in the chalk, and he had never known one to fail for drawing water at a short distance from the river. The expenses of a chalk water scheme at Ely would be of the same character as those at Saffron Walden, with the exception of expense for the softening process, which was to be adopted at the last named place.

In cross-examination by Mr. Marshall, engineer said that he had no objection to raise to the plans of the Board (which he had not seen till that day), except as to the filtration. He agreed at the meeting of the Board that the chalk was always a safe source to look to for water. Water from the chalk was always found at the bottom of hills. The quantities of water from the chalk and the fields, the form of rain was nearly the same. He had no theoretical objection, and not much any experiments as yet to ascertain the quantity of water that could be obtained from the chalk at Ely. Speaking generally, he was extremely in his experience in other chalk districts, that there was a sufficient supply of water in the Newmarket chalk hills.

Archdeacon Emrar having commented on the evidence by which his scheme was supported,

Mr. *Marshall* said that he was glad to find that the gentleman had repeatedly expressed their conviction that it would be unwise on their part to expend a sum of £15,000, or more, on water supply of a small and not opulent place like Ely. Even with all the skill which the English brought to it in these days, a handsome supply might be obtained from the water from the Thames, purified by mud filtration. On Thy, Dr. Frankland had said that the water was as good as that from the Lea or the Lea and Ware, and pronounced it to be fit for drinking.

Mr. *Hopkins* remarked that Dr. Frankland had not always expressed satisfaction with the Thames water.

Mr. *Marshall* observed that Dr. Frankland's conception of purity was founded on chemical considerations; whereas Thy had been free of a pestilent medical man.

The Chairman referred Mr. Marshall to Dr. Thy's medical opinion of the samples of water taken from the Lea, which was also condemnatory.

Mr. *Marshall* intimated that, rather than incur the responsibility of undertaking a water scheme, the Board would stand by it, and let the Central Board carry it out and take the risk.

The Inspector intimated that a mandamus might be obtained against the Local Board to compel them to carry it out.

Mr. *Marshall* said that a mandamus might be mischief had as yet resulted from the use of the river water, and that the town would recall to future if the Board were to adopt the chalk scheme. The prosperity of resulting to the town from a water supply was beyond all question. The Local Government Board, by their having given their sanction for a new issue from the river. No person whose name was being inquired into by the Local Government Board, who, on the other hand, might have told the Local Board to go ahead in their boldness.

The Inspector pointed out that this would not have been the case if the Board had not before them the report of the Local Board had case. He had been very much impressed by the Public Health Act.

Mr. *Marshall* said that, in his employers' point of view, the chalk supply was not the main question. The great thing with him was as to the completion of the present supply. They wished to compel Cambridge to divert the sewage from the river. He looked upon the conduct of Cambridge in this matter as a scandal; it was a deliberate ignoring of a public duty—a daily infringement of an Act of Parliament. He would move the Local Board that they could attain the end in view by the direction of the river water as by passing it into a well by Ely. Nevertheless, if the Local Government Board were not satisfied with this, he might say, on the part of the Board, that they would, upon an intimation from the Board above, they would be prepared to proceed with the construction of a shielding reservoir, although they would not construct them of the town good will.

Although the previous might be very useful sometimes, in removing the opposite of the water in them to the effects of light, heat, and air would cause the development of animal and vegetable life, and their appearances at times would be rather disgusting. The Board had had a meeting that morning at which the subject of the Lighthouse Illumination degree, beyond question, and in fact—as regards the question embarking on the chalk water scheme. If they carried out the scheme they proposed, they would be setting on a complete experimentation, and would be in much the same place as the sanitary catalogue than the University town.

The Inspectors said he had listened patiently to the evidence brought before him, also to Mr. Marshall's speech. He should read through his notes, and report to the Local Government Board, who would communicate their decision to the Local Board.

The inquiry then closed.

PROFESSOR TYNDALL AND LIGHTHOUSE ILLUMINATION.

The following letter of Professor Tyndall will be read with interest, containing as it does the history of the lighthouse illumination dispute, beyond the mere question of economy:—

Commander of Atlantic steamers had long deplored the absence of any light on the Irish coast between the Fastnet and the Old Head of Kinsale. The captain of a famous Canadian described to me, on the spot, in the autumn of 1867, the anxiety he experienced when passing over those ill-famed miles in thick weather. It was at length resolved to establish a light on the dangerous promontory of Galley Head. The Irish Board of Inspectors of Irish lights recommended, and I think, at a meeting of the Board, decided to erect a first-class catoptric light, revolving once in two minutes, and a flame-bearing, if not a flash, in the world. Soon after its completion it was visited by a Committee of the Elder Brethren of the Trinity House, attended by their engineer, who subsequently wrote a report of his visit. It could not be called a public report; but it was communicated in manuscript to the Board of Trade and was quite in accord Boards, which I was permitted to read. Mr. Douglass was quite in accord with the recommendations which Mr. Brevoort and Sir James Douglass had made in relation to the inventions of Mr. Wigham. The Board of Irish Lights, having good reason to hesitate before accepting as final the criticisms of the Trinity House Engineer, asked me to read his report. Hesitation, courteously offering at the same time to put their steam yacht, the *Princess Alice*, entirely at my disposal. I accordingly spent twelve days in Long Island, Cork, and Galley Head light. Mr. Douglass, Mr. Brevoort, and Mr. Wigham were also present.

The Galley Head light is revolving catoptric. Four tiers of lenses are mounted one above the other; each tier presenting its own lenses, and the weather darkness, these lenses are flashed in succession; the power of the single light being sensibly doubled, trebled, or quadrupled, according as the light is the uniform, or the combination of two, three, or four tiers of lenses. The lenses are of barrows varying from 19 to 24 inches in diameter. The light is placed in the centre of the apparatus, the lighthouse, is raised over eighty feet above the sea. The light is thus instead of being permitted to pass the meridian without interruption, is flashed automatically four times, in each of which the full intensity of the flame is put forth. Having made a series of 20 experiments at different distances (15 miles for the greatest), the vessel sent me to a point 10 miles, where, the earth's rotundity coming between me and the light, it disappeared. I then steamed in the direction of the light itself until I could read the time by my watch, almost as if it were close at hand; while after the light had "set," every pulse of the flame was visible as a gleam in the surrounding darkness. As regards power and distinctiveness combined, no light previously invented to the mariner can be put in competition with the Galley Head quadruple flash. And, as before, I am happy to the commanders of the great ocean steamers concurred in the opinion that the Galley Head light would be a boon to navigation of the most marked and valuable kind. In the latter case, Captain Lund calls it a "splendid light, easily distinguished from any other in character." Captain Brooke, who had the charge of viewing the light in very hazy weather, calls it "a most excellent light." Captain Hewett, of the *Cunard*, calls it "a very fine light." Captain Cleeves describes it as "a most powerful, beautiful, and unmistakable light."

HOUSE OF LORDS.

MONDAY, May 14.

A petition for additional provision in the Ipswich Gas Bill, from the Ipswich Gaslight Company, and the Corporation of Ipswich, together with the proposed clauses and amendments, was read, and referred to the Examiners.

HOUSE OF COMMONS.

MONDAY, May 7.

THE BOARD OF TRADE AND PROFESSOR TYNDALL.

Mr. Gibson asked the President of the Board of Trade whether it was true that Professor Tyndall, F.R.S., had resigned his position as Scientific Adviser to the Board of Trade on Electrical Standards; and, if so, what reasons he had assigned for so doing?—Baronet Sir Michael Hicks-Beach replied that Professor Tyndall recently resigned the position he had held as Scientific Adviser to the Board of Trade, under circumstances which were given in a long correspondence between Professor Tyndall and the Board of Trade, and the production of which the right honourable gentleman would perhaps wish to move.

Mr. Gibson gave notice that he would move for the correspondence.

TUESDAY, May 10.

A petition against the Dumbarton Water Bill was presented from Lord Blantyre.

LIGHTHOUSE ILLUMINANTS.

On the motion of Mr. Gibson, a copy was ordered of correspondence on the subject of a proposed investigation into the respective merits of gas, oil, and electricity as lighthouse illuminants, including correspondence between the Board of Trade and Professor Tyndall, F.R.S.

THE ELECTRIC LIGHTING AT THE HOUSES.

In Committee of Supply on the Civil Service Estimates, the vote of £21,136 to defray the sum of £37,136 for Public Buildings at Home, with the exception of £16,000 for the Houses of Parliament.

Mr. Gorst, complaining of the recent introduction of the electric light into the Law Courts, asked whether any other than the Edison Company had been invited to tender for the lighting; and whether further tenders would be solicited before the particular companies to whom the electric light was used in other parts of the building were chosen.

Mr. Shaw-Lefevre explained that as a proposition had been made to the Edison Company to light the dining-rooms and library of the House experimentally for a very small sum, he had thought it desirable that members should see what the effect would be. It did not appear to him that electric lighting in the present stage was a proper subject for competition. When electric lighting for the lighting of the Law Courts, he had considered the whole subject, and had decided that he could not invite competition. It appeared to him that the best plan to select the system he thought most likely to answer. He had, therefore, considered that the Edison-Swan system was the best adapted to the Law Courts. Between the Swan and the former Edison system of the Law Courts there appeared to him not much to choose; but the Edison system in the House. Whether it would be ultimately adopted he could not say. Nor would he consult the comfort and wishes of honourable members. Nor would he consult the comfort and convenience of the public, but would consult the interest of the public and especially of the ratepayers. He understood from Mr. Gibson that it was Lord Thurlow's shareholder in the Swan Company.

Lord R. Churchill explained the suggestion that he might be interested in the Swan or some other company; but the Swan Company had, he said, lighted the Law Courts in a manner which had satisfied everybody, at a most moderate expenditure, and on this account they certainly deserved some credit from the First Commissioner of Works. There was complaint of the Office of Works in that, without saying a word to any of them, the Commissioner had concluded an arrangement with this Company, and had allowed him to defend it during nearly the whole of the Session, and, with one exception, the greatest advocate they could possibly give to an electric lighting company. It was very much all over the world, wherever electric lighting was carried out. Even the Edison Company were themselves, likewise, Directors of the Edison Company. Though he was not interested in these companies, Directors of the Edison Company. Though he was not interested in these companies, Directors of the Edison Company. Though he was not interested in these companies

ELECTRIC LIGHTING MEMORANDA.

The different Electric Lighting Companies which retain pretensions to an active existence are making themselves exceedingly troublesome to the public authorities of nearly every town in the Kingdom. The country newspapers are full of reports of Town Council and Local Board meetings, wherein proposals emanating generally from the Hammond-Brush or the Edison Company are discussed with more or less show of electrical learning. At Ipswich, for instance, the Hammond Brush, the Edison, and the Gulcher Companies have all (simultaneously) asked sanction for applications for licences, or given notice of intended applications for Provisional Orders. The electric light has not yet appeared at Ipswich, and the majority of the Council are afraid of the cost; but here again was heard the familiar tag about other towns trying electric lighting, and "Ipswich ought not to be behind." It might well have been thought that one experiment would be sufficient to prove the advantages of any system, or the reverse; yet the localized "brushes" are still as indefatigable in soliciting opportunities for trying "experiments," as though the notorious 2000-candle power lamps were always fresh and new in every fresh place. Volumes have been written on the adventures of books, coins, and other portable property; but, judging from the way in which Brush lighting starts up in one place after having been tried and rejected in another, the travelling experiences of a workable Brush dynamo machine must be quite as worthy of record.

At the time when so much stir in the matter of licences and Provisional Orders for electric lighting is agitating the provinces, reports of the general meetings of the Electric Lighting Companies in London are full of instruction respecting the other side of the picture. The principal work done at these meetings is usually certain alterations in some of the Articles of Association, in order to obtain Stock Exchange settlements. This is always put forward as the most important object to be attained. Business may or may not be coming into the concern; the work or contracts in hand, if any, may or may not be profitable; but so long as a little financing can be done, who cares? There are seldom any other resolutions to be passed at these meetings; and, it is scarcely necessary to observe, there is never any dividend to declare. The report of the first general meeting of the Birmingham and Warwickshire (Brush) Company is a good specimen of many others. This undertaking is a child of the Hammond Company, which is a child of the obligations of this hopeful family are even more obscure than most genealogies of another kind. The original stock-in-trade of the so-called local Company (whose meeting is, of course, held in London) was a valuable "concession" of the right to the Brush patents in the district named in the title. Soon afterwards it was discovered at the London office that part of the borough of Birmingham was not in Warwickshire at all, and so it became necessary to expend a further sum of £20,000 in the purchase of similar rights in Staffordshire and Worcestershire. Now the Chairman has an inspiriting tale to tell of the receipt of one order for lighting on exhibition, and of several most promising inquiries. Therefore the Company is flourishing, although the question of dividends is still in abeyance.

Sufficient mirage has already been made of Lieut.-Col. Festing's ecumenical triumph in the so-called lighting of the South Kensington Museum by electric lamps, as compared with the previous gas lighting; but it is possible that recent experiences at the Birmingham Town Hall may be similarly misinterpreted by electric lighting partisans. It has been widely admitted that the state of the atmosphere of the Hall during the recent Musical Festival was greatly superior to that observed on previous occasions of the same kind. This time the Hall was lighted by incandescent electric lamps, and the improved effect was, of course, wholly set down to the change to this system from the foul, polluting, suffocating combustible supplied by the Corporation Gas-Works. This was a great lift for electricity, and a great discredit to gas, so long as the first crude results remained without other explanation. Something has since been stated, however, which the audience at the Festival could not be expected to know—namely, that, in view of the event, a thorough overhauling and rearrangement had been made of the ventilation of the Hall. Previously the fresh air inlets were very inadequate, and generally took the form of draughts; while the openings in the ceiling for the escape of hot and vitiated air were only competent to discharge the contents of the Hall once every four hours. Added to this, the heating arrangement consisted in warming air taken from the Hall and returning it again, instead of admitting a fresh allowance from without. Now, however, by new ventilators making use of currents induced by gas-jets, the atmosphere of the Hall is changed completely every half hour; and thus the highest temperature under the ceiling is easily kept about 40° lower than before. The superior comfort of the audience at the Festival is thus easily accounted for without ascribing to electric lighting a virtue which it does not possess. Indeed, it will be seen that the vitiated gas is one of the principal agents in effecting the beneficial change in question. It will only be following established usage, however, if in future all the credit of supplying fresh air to the Birmingham Town Hall is appropriated by the electricians, without a word of acknowledgment to the ventilating engineers, but for whom the atmosphere of the Hall would have remained as foul with incandescent lamps as it used to be with gas.

ELECTRIC LIGHTING MEMORANDA.

From all parts of the country intelligence comes to the purport that the Board of Trade will not have to grant (simply as many Provisional Orders under the Electric Lighting Act as at one time appeared to be demanded. The local authorities of Leicester, Rochdale, and many other important towns, together with nearly all the London Vestries, have decided to sacrifice the preliminary expenses incurred by the Act, and to abandon their proceedings, at least for the present. Mr. Chamberlain's declaration to the effect that powers would not be granted to corporations unless it offset of lighting some of them, has had the principal motive in taking action was of speculators, whose from speculative intentions. The Rochdale Town Council, like many other local authorities, had endeavoured to obtain some precise information that might serve as a basis of action, or at least of argument. With this object they obtained a report from Sir Charles Bright and Mr. Muirhead undertaking in the centre of the town. This report has been published, and amply testifies to the skill and care bestowed upon the question by the eminent authorities already named. According to them, the establishment referred to could provide incandescent lighting at a cost to the producer of exactly 16s. 0¼d. per lamp per 1000 hours per annum. The lamps would, of course, be equal to 20-candle power. The report obligingly compares this scaling with the cost of gas, which is assumed to be, at 4s. per thousand cubic feet, just £1 17s. 6d. for the same number of hours of lighting by a burner consuming 5 cubic feet per hour, and liberally allowed to afford the light of 12 candles. It was but a poor compliment to the eminent electricians who had made themselves responsible for these statements, that the Corporation, upon receiving this report, immediately and unanimously passed a resolution not to proceed with their application for a Provisional Order under the Act. But they mean to imply any distrust of the figures that had been so carefully worked out by the electricians, without a word of acknowledgment to the ventilating engineers, but for whom the atmosphere of the Hall would have remained as foul with incandescent lamps as it used to be with gas.

symmetrical with the parallel is rendered incomplete and unsatisfying by the absence of a meter for the electrical supply. The Company's charge, if they ever commences business, will probably resolve itself into a fixed sum per lamp per quarter, and will be stated at this minimum. If, in addition to this, consumers are expected to find their own lamps (which cost 6s. each, and require renewal at least three times a year), the Corporation must not tremble for the future of their gas supply in view of the competition of the Compton-Windsor Company.

The American correspondent of *The Times* has recently given a hopeful account of Mr. Edison's proceedings in New York; and it is significant of the comparatively feeble interest taken by the investing public in such matters, that a communication which at one time would have convulsed stock markets everywhere is now practically unnoticed. The great inventor is, of course, doing wonders; but that is his usual occupation, and is therefore not news. One of his children—the Edison Insulated Company, a concern which is devoted to lighting mills and warehouses by installations contained on the premises—has recently declared a dividend of 30 per cent.; to which special attention is drawn as being the first profit earned by any company for lighting, pure and simple, without help from the sale of plant or concessions. We are glad, moreover, that Mr. Edison's knowledge of the conditions of the electric light question in England is complete. To his mind the price of gas here is the one factor in the problem which requires solution. The writer goes on to remark that "it is in this problem to which he has applied himself with so much success." There is evidently some mistake in these two sentences, but we cannot undertake to point it out.

The Electric Lighting Committee of the Hull Corporation, who have employed Messrs. Siemens Bros. to light a portion of the town under the provisions of the Local Board Acts, are not much pleased with the result that can be obtained from the Brush system. As will be seen by the report in another column, a special meeting of the Hull Committee was recently convened for the purpose of drawing the immediate and serious attention of the contractors to their "non-compliance with the terms of their electric lighting contract;" and, having done this, they adjourned further consideration of the matter for 24 hours. At Cleethorpes—the scene of the latest attempt at public lighting by a Brush Company—the Local Board are much incensed with the failure of the experiment. The incandescent lights have been condemned on all sides, and the contractors have promised to replace them with arc lamps. Hero, however, at Chesterfield, the authorities, having begun to experience the ways of electricians, have been by no means the slnps of a dimly Order, which has been transmitted to the Corporation, and has also been explained and commented on in a local newspaper. The matter of most general interest in these documents is the basis upon which rates for electrical services are to be levied. The undertakers wish to reserve power to elect whether they will charge consumers by quantity or time. They have found it necessary to define a unit of "electrical energy," which is the energy contained in a current of 1000 amperes flowing under an electro-motive force of 1 volt during one hour. Although this unit is the energy required to feed 20 incandescent lamps of about 15-candle power. The Corporation contemplate a charge per quarter of a year, of £1 10s. for any quantity up to 100 units; "and for each unit over 100 units, 8d. per unit." According to this scale, it is computed that the Company's maximum charge will be equivalent to gas at 6s. 8d. per thousand cubic feet. In case consumers are charged by the number of hours, the price is to be levied on the supposition that the consumer uses the maximum current specified by the Company. Thus, although it may be interesting to attempt a comparison between the charge for electricity and that for gas measured by meter, it is

The writer goes on to remark that "it is in this problem to which he has applied himself with so much success." There is evidently some mistake in these two sentences, but we cannot undertake to point it out.

The Electric Lighting Committee of the Hull Corporation, who have employed Messrs. Siemens Bros. to light a portion of the town under the provisions of the Local Board Acts, are not much pleased with the result that can be obtained from the Brush system. As will be seen by the report in another column, a special meeting of the Hull Committee was recently convened for the purpose of drawing the immediate and serious attention of the contractors to their "non-compliance with the terms of their electric lighting contract;" and, having done this, they adjourned further consideration of the matter for 24 hours. At Cleethorpes—the scene of the latest attempt at public lighting by a Brush Company—the Local Board are much incensed with the failure of the experiment. The incandescent lights have been condemned on all sides, and the contractors have promised to replace them with arc lamps.

The Chesterfield Corporation, however, have been by no means slow to experience the ways of electricians, and have begun to sign the contract handing over their district to the latter for a definite time. We have not heard from Chesterfield since the Company have yet redeemed their reputation. The electricians, however, have a firm friend in the Town Clerk of this place, for we observe that this gentleman is always willing to oblige inquirers with a good character of the contractors' "efficiency and economy." As the statement does not agree with the published opinions of Alderman Gee on the same subject, we should like to be informed whether at the time this letter was written the contract in question had actually been accepted by the majority of the Corporation.

It is suggested in the *Solicitors' Journal*, that local authorities who have decided not to avail themselves of the Electric Lighting Act may nevertheless have power to contract with any person for the supply of electric light in their streets, under the well-known provision of the Public Health Act, 1875, section 161. This is manifestly true, and the new law' him during all the hours of supply. Thus, although it may under previous general legislation. But our legal contem- poraries appears to forget that it is for an undertaking for a private lighting that the question of the Board of Trade is

required." There is no Order necessary for public lighting, or even for private lighting by a company of adventurers willing to take the same risks as an unauthorized Gas Company.

Notwithstanding the support afforded by several local celebrities, the Dalziel Electric Light Company—one of the Brush swarm—has come to grief at last. The concern has had a brief but troubled existence, having started with a nominal capital of £10,000, of which £16,280 has been actually called up. An attempt is now to be made to sell the plant and goodwill as a going concern; but the result of this proceeding is not difficult to foresee. A professional shareholders is to be appointed with a committee of five. This is but the beginning of the wreckers' season in the electrical speculation.

SOME NOTES FROM AMERICA.

(FROM OUR OWN CORRESPONDENT)

New York, Nov. 22, 1882.

The scientific world has just been called upon to mourn the loss of one of the most distinguished workers—a gentleman who, by his original researches and patient investigations, has made himself honoured throughout the civilized world. Professor Henry Draper will be regretted the more that he has been taken away while in the prime of life, and at a time when it seemed as if his labours were but begun. Those who have followed the course of astronomical photography, and the work he did in this connection has made for him a world-wide reputation, will know that it was not unreasonable to expect that he was the discovery yet to be given to the sun. This was in 1867, after a long and patient investigation. He was then sent by the Government to Peru, to observe the transit of Venus, but was unfortunate in the weather, and failed to secure a picture. The latter applauded his discovery; but the Britishers were slow to acknowledge the correctness of his claim to the honour. It was a long time before Professor Draper's habit, whenever the sun in its business appeared in the heavens, to enter the Observatory and take a picture of it. Many of these pictures he invariably gave his guests a practical exhibition of. On the evening before his illness assumed a serious aspect he showed the members of the Society, and had a quite unique display of the objects of interest. The following morning the Professor was taken seriously ill; yesterday at 10, and under this he rapidly sank. He lingered until the morning of Sunday, the 20th inst., when he passed away at the early age of 45.

The electric light companies in New York continue to make a little progress, but perhaps not as much as they have accomplished in the early days of the year. The United States Company, controlling the Maxim patents, is supplying in the city four stations, from which they have one 25 and two 200 horse-power lights. At one station they have a 50 and two 200 horse-power lights working, the capacity of which is said to be 200 arc and 2500 incandescent lights, and I have been informed that the total exactity of the Company's plant is further 2170 lights of 20 candle-power. The Company states that they have 1500 incandescent and 511 are lights now in operation, including 72 used for street lights. It is also stated that they have in the city 141 miles of are lights give the highest, or perhaps more correctly speaking the least disagreeable light of any are lamp with which I am acquainted. The lamps with comparative steadiness, and the unpleasant visual pressure are so painfully apparent as in the Brush lights, I do not, however, wish to give you the impression that the Maxim lights are free from defects. On the contrary, I have witnessed many failures during my visits to the stations where the lamps are in operation in inferiorly lighted streets. Take the case of the Canal Street, the prospect is about as gloomy as one would wish to see. The Brush Company at present is about as gloomy as one would wish to see. have witnessed the capacity of their present plant, and are not willing at this time to make any extensions. The Company controlling the Maxim patents are now erecting a station, according to their account, they contract for the saking is that Mr. Brush is doing little at present. They claim to have 1000 lights in operation, till it is known what will be the result of the experiment. This Company supply direct lamps, and they claim to have not 211 day lights in large stores and about 500 night lights.

Some reporters of the Daily Papers have been going round interviewing the parties who are using the Edison lights now supplied from the Company's central station. Few of the consumers appear to be satisfied with the result of the experiment. One of the consumers was not resting there to say anything, so they would call again to see it. The general complaint seems to be that the light was so brilliant as one moment and dim the next. One party did not think it was a gas flame. The reporter thought it was not a light by which to read a gas flame. The reporter thought it was not a light by which to read a gas pea, but added: "We like it better than the light was not so much as anything." I suppose this is what "dim gas" means. It does not look like a commercial basis." The cause of the dull or feeble power of the lights is said to be that the Company can run only one of their six engines at a time. It will be remembered that one of the advantages of the Edison system is that where several dynamos are in use the electricity from each of them is run into one main conductor, the several engines of the several dynamos into one main main. At least this was one of the advantages claimed for the system on paper. It is now said that as they attempted to run two dynamos, that as it was impossible to run the engines at the same speed—they would not work smoothly; the one engine driving the former to become stopped as with reelse; the result, of course, being a miserable forked flame. Further, people are beginning to realize that the Edison light is not so luminous a substance as they have been led to believe. The truth is the number of deaths caused by water gas in New York City almost equals the number of new patients in hospitals. The *Sanitary Engineer* declares that 11 deaths have occurred in the city in consequence of the use of this gas, since the 1st of January. If there is to be a fight between gas and electricity, this is a heavy load for the gas industry to carry to the conflict. A few evenings since a man was found lying on the walk in front of a hotel at two o'clock in the morning. At about the same hour a lady observed a colour of gas was perceived in the vicinity of the apartment in which the lady was asleep. On turning on the gas, the man was found to be dead, and the man died shortly after he was discovered. Of course it is stated that the man died from the gas—in fact, this is the stereotyped explanation of these disasters; but it seems strange that a man who had lived in the city for some time should not have known better than to have put a gas flame in a closed room. The truth is that the gas—making a large percentage of carbonic oxide is very liable to be blown out by an ordinary draught; and these accidents, I think, are not occasioned by people blowing out the gas, but by the flame being extinguished by some draught or current of air. Another case—a policeman in the city—was found in a lodging-house in Chatham Street, asphyxiated by gas; death followed in a few minutes. A removal into the open air. Strange that a man so used to the vapor of a large city as a policeman must be, should be guilty of such gross stupidity as to go to bed in a room in which gas, in the aromatic of these accidents which appear in the Daily Press, or rather inside is made of the fact that its water gas that creates such havoc; and surely the Company have no authority has to bear the burden of the sins of our water gas friends. But the managers of the electric light companies let these opportunities for a word in season on the gas business pass "unimproved." On the contrary every such accident is graphically described in large type in the journals devoted to the cause of the new illuminant. So the public are being "educated" to the belief that gas is a death-dealing substance.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [Oct. 17, 1882.

EDISON LIGHTING IN FRANCE.

IN a recent number of the *Revue Industrielle* M. Ph. Delahaye has ran article on the progress of the Edison lighting movement in France, which contains so much side argument, and is so badly expressed, that it deserves translation into English in its entirety. The length of the sentences, however, against this method of treatment, and already generally known. M. Delahaye begins by telling whatever may be the opinion of the public during the past few years with the significance has tolerated into business certain images which do not conform to the elementary principles of true industry. It has been incessantly believed, until recently, that any enterprise worthy of being taken up by a joint-stock company should at least rest upon a serious basis, and should have been proved to give a sufficiency of practical results before an appeal is made to capitalists. Laboratory experiments, even when in the guise of working installations, should only be regarded as encouragements to adventurous spirits, who are notable to valuer gains; it is not usually permissible to augur from the particular to the general, and to proceed to work on a large scale upon the authority of a few limited experiment. Still, however, every one says now-a-days that time is money; and the old method has the inconvenience of employing a great deal of this capital. Consequently, inventors of a new motor made than they are always to us in all their maturity; and the public are asked to defray the cost of a frequently inconsistent and precipitated education. By reason of the peculiar opportunities which it affords for speculation, electricity has been selected as the subject of certain financial projects which appear to threaten its future; and it is from this reason that has instigated M. Delahaye to discuss and consider—not as an enemy to electricity so much as a foe to speculative electricians.

At the beginning of the present year the speculative fever began in France by the formation of a company for the utilization of Edison's system by the aid of electricity, whereby a great number of benefits were to be conferred upon mankind at large and the company in particular. The company is now dissolved, and for some time after this fallen electrical speculation made its home chiefly in England. Recently, however, the fever has reappeared in France, although it is as yet confined to the provinces. The Edison system of electric lighting is the cause of this new outbreak, since there is no French invention of the kind sufficiently potent to draw money out of the pockets of French capitalists. Therefore the names of the shareholders in the new concern is declared for expatriation. A Continental Edison Company has been formed in Paris, with a capital of one million sterling, which possesses all the European rights of the inventor, and takes 45 per cent. of the capital of all subsidiary companies formed under its auspices. The principal work of the Company will therefore be the establishment, in all quarters of Europe, of companies, who will be made to pay dearly for the right of buying and using the American machines and lamps. It is to this method of exploitation that France is indebted for the Bessancon Electric Lighting Company, upon which we have already commented, and for the Edison Electrical Company of Dijon. The prospectus of this enterprise appears to have been M. Delahaye's incentive to write the article now under notice.

It is pointed out to begin with, that the demonstration given in this prospectus of the economy of electric lighting as compared with gas at Dijon rests on a false assumption that the price of gas at this place is 45 c. per cubic meter, whereas the legal price is only 32 c. Anyone who is desirous of ascertaining the income for electric lighting is complained of, and with reason, since it consists in stating what would be the cost of gas at 45 c. per cubic metre to obtain a light equal to the Edison 16-candle lamps. This, as M. Delahaye points out, is the wrong sequence of reasoning, because the electric lamp is the chief aim, and not the gas, which is already in position. It so happens, moreover, that gas-burners of 16-candle power are rarely met with in private houses, where the rate of consumption per burner is more frequently 6 or 4 cubic feet per hour. Therefore to base an estimate of economy upon a supposed hourly consumption of about 8 cubic feet for every burner, is contradictory to every-day practice; and to attempt to obtain the number of burners in use in a town like Dijon by dividing by this fantastic figure the quantity of gas sold, is absurd. M. Delahaye repeats here

A PRIVATE ELECTRIC LIGHTING WORKS.

MR. W. Spottiswoode, P.R.S., ex-President of the British Association, has given practical evidence of his belief for electric lighting by following the example previously set by Dr. Siemens, and provides the luxury of lamps for his country residence near Grossbrook. The record of the installation, as given in the *Engineer*, is not perhaps extended to remove the prejudices of those who regard this method of lighting as at present a costly toy. It has been constructed in the grounds, for the purpose of supplying light, water, and power for the house, stables, and gardens. A 12-horse power (nominal) steam-engine, of the latest pattern, supplied with steam from a vertical boiler, and all the necessary appliances for working the extensive machinery, electrical and otherwise, are placed in charge of an efficient engineman. The whole system of lighting which comprises four circuits, each of 50 Swan lamps, and four large arc lamps placed outside the dwelling-house, and ten more in the park, is under the control of an electrician. Telephonic communication is arranged so that the owner of all this apparatus can listen at will to the exact hum of the dynamos, while rejoicing in the power it produces. The engine is fitted with a speed governor, known as Deadman's velometer, which is said to regulate the speed of the machinery so effectually that the engine driver does not know whether the dynamo is doing any work or not. The panel is believe in the scientific effects of the lighting, not being responsible for the expenses. It would be deemed impolitic, perhaps, to ask for an appendix to the narrative of the *Engineer*, stating the cost of the establishment, and the working charges, not omitting a compensative record of the amount saved in the items of gas, oil, or candles.

ELECTRIC LIGHTING MEMORANDA.

The promoters of electric lighting companies are usually difficult of access, and the speculators who have taken shares in these ventures are not easily disturbed as long as shares can be bought and sold; but in a recent number of the *Electrical Review* there is a letter from Mr. Charles T. Wright which cannot well be overlooked. This gentleman (who, if we do not mistake, is connected with the British Electric Light Company) betrays something very like an accusation of fraud upon the persons who issued the prospectuses of nine of the Consolidated Brush Companies, in respect of their statements regarding the licenses for the Lane-Fox lamps. It appears that all the prospectuses in question contain the assertion that the stock-in-trade of the Companies includes the exclusive right to use and sell the Lane-Fox lamps in the districts referred to. Mr. Bright asserts that, so far from this being correct, the British Electric Light Company possesses prior rights as to these precious lamps; and he thereupon indulges in gloomy remarks about directors and vendors having, in his experience, been compelled to refund money contract has expired. The Hammond Company have given invested on the faith of flying prospectuses. Now the question notices wholesale of their intention to apply for licenses for arises—Who is to move in a matter of this kind? Here is an sessation of fraud, or of criminal negligence, levelled by a sufficiently well-known man against a swarm of directors, solicitors, and other officials connected with public Companies, some aggregate capital amounts to millions. The allegation is specific and unmistakable, and how is it to be met? For those who, like ourselves, regard the first and second claim to exploit the wonderful lamps in question as of about equal intrinsic value, this looks like a "very pretty quarrel as it stands;" and we shall gladly take up a place in the ring for the purpose of seeing it through.

The Vestry of St. George's, Southwark, held very advanced notions respecting the manner in which the Electric Lighting Act should be worked by local authorities. At a recent meeting of this important governing body it was resolved that application for a license or a Provisional Order for supplying electric lighting should not be made by them at present. This practical resolution was followed by another, to the effect that any independent applicants for Provisional Orders or licenses shall be opposed, unless they will consent to hand over to the Vestry one-half of their profits beyond 7½ per cent. This brilliant stroke of administrative genius has already found its way to fame, and has awakened an echo in sympathetic minds even so far as Worcester. The proposal to be admired for its boldness, if not for its originality. For the former, because it starts with the assumption that a Company undertaking the electric lighting of the parish will actually realize more than 7½ per cent. profit; and, with the approval of the Board of Trade, will be found willing to bribe the Vestry with *one-half* of all the gains made in excess of this figure. Unfortunately for any claims to originality which the authors of this notable decree may fondly cherish, it is merely a mutilated copy of the regulation under which the gas supply of Paris is conducted. This experiment, as the inhabitants of the French capital know by sad experience, has resulted in keeping up the price of gas to nearly the London standard, and in forcing a generation of discontented consumers and shuffling administrators. There is fortunately not much probability that the St. George's Vestry will obtain immortality on further than the Gaseous scheme, which would make of the ratepayers' representatives, and natural guardians, partners with a band of exacting speculators.

At last it has been notified by the Hammond Company that they cannot do anything to improve the lighting of Chesterfield by the Brush and Lane-Fox lamps; and, simultaneously with this declaration, Alderman Cree, who has waited patiently while the experiment in question has been dragged on for a year, has written to the *Standard* with a view to the insertion of special clauses for the protection of the town in any Order that may be eventually issued. field Town Council, that 'the lighting is a pronounced A local Brush Company and the Edison Company appear to failure. Mr. Hammond has visited Chesterfield repeatedly, be the only competitors left; and it is even doubtful whether and told the inhabitants of his intention to make the town a these will trouble the Corporation. show piece wherein the ability of his Company to undertake public lighting should be brightly manifested. This has indeed, been done so well on paper, that, even within the last few days, an Alderman of Hanley could speak in public of the successful lighting of Chesterfield by electricity. It now remains to be seen whether any notice will be taken of Alderman Gee's statement of facts, as opposed to the misrepresentation that has been allowed to pass current for so long. It is a curious commentary on an observation of the Alderman—that not one instance has occurred of the interference of electric lighting into any shop or house in Chesterfield, notwithstanding the persistent energy displayed in this direction by the Hammond Company's agents—that a memorial has just been presented to the Town Council, by a number of ratepayers, asking for facilities for the general supply of electricity for lighting. It would be instructive to learn how this precious memorial was originated and managed. The Town Council, however, have decided to apply for a licence under the Act, although it is scarcely likely that they will continue to move in the line of trammels in the readiest manner. Hence each means because the pole of a huge electrifying machine, lying in wait for the unwary individual who should complete the circuit by stepping upon both the metals at once. The state of affairs here described was first made manifest to the public observed to display sudden fire and unrivalled liveliness of action when crossing a certain part of the road. A crowd was soon gathered opposite the "great horse-exhilarating station," as a newspaper report terms the spot in question; and before long the cause of the mysterious display was discovered. Lucidity to harm was done; but the Edison Company had a fine opportunity for pointing out that if the Brush current had taken a similar course, every animal, instead of being merely frightened, would have been killed on the spot. It happened that a workman employed by the Brush Company was killed about this time by touching the wires attached to a lamp; and the public mind is somewhat distrustful of the system in consequence. Mr. Edison says that all such wires should be buried out of harm's way; but this appears to be what he has not been able to do with his own leads. It is therefore a question how intense currents can be insulated so as to combine with safety, taking due account of the factor of carelessness and blundering.

Some very peculiar business is at present going on between the Faure Electric Accumulator Company and M. Philippart, their promoter or patron. This individual and his friends hold the controlling interest in the Company, and he also has "an arrangement" with another Company, who, it is stated, own the only accumulator fit to compete with the Faure battery. M. Philippart has now ordered that the Faure Company shall cease to exist as an industrial concern—a decision which they had obtained at great cost from the parent Company, which he did not think was worth much, as "electric lighting is now in rather low water." All of the Devon and Cornwall Company was fain to admit that their business receipts up to the present time amount to the small sum of 200 10s. and no more. After this, who should deny that Brush lighting is a paying business?

In connection with the present scare among Brush Companies, it may be noted that a strong point with the petitioning shareholders is the misrepresentation of the Company's position in the matter of the licences for the Lane-Fox lamp. All these concessionary Companies, which are now in such a bad way, were started in business with a stock-in-trade consisting of a guaranteed connection between British and Lane-Fox lamps. Unfortunately, the word *exclusive* was inserted in the prospectuses with reference to both systems, whereas there existed an assignment to the British Electric Light Company of the precious Lane-Fox patent. It now remains for the Court to say whether this blunder, which is now admitted by the incriminated Boards, amounts to a false pretence or not. It is curious to note that the excuse proffered by the respective Chairmen, the evidence of a previous agreement as to what they should say. Every man declared in effect that the mistake was of no importance, because the supposed right to the Lane-Fox lamps is not worth the smallest coin of the realm to anybody. Thus the ingenious inventor's (?) fame is sacrificed upon the altar of expediency. Mr. Lane-Fox has now a good opportunity for soothing his wounded vanity by asking these gentlemen to show what value the other part of their concessions possesses.

An exciting discussion took place at the special meeting

Journal of Gas Lighting, Water Supply & Sanitary Improvement
Nov 14, 1882

ELECTRIC LIGHTING MEMORANDA.

The influences of the Birmingham Town Council has at least extended as far as Wolverhampton, for at a recent meeting of the Town Council of the latter place it was decided to follow the Birmingham lead in the matter of the Electric Lighting Act. The Wolverhampton authorities have passed through the period of doubt and inquiry experienced by their more populous bodies all over the Kingdom; and in their difficulty they applied for guidance to Mr. J. N. Shoolbred. This gentleman's report did not convey much comfort to his anxious clients, for although he told them something about the arrangements of such an experimental electric lighting installation as everybody saw or heard of before the Act came into being, he naturally failed to prove that any such undertaking would be either safe or profitable. He and the Borough Engineer appear to have set their minds upon a somewhat in the Brush model. This proposal is mixed up in some way with a project for the amalgamation of the two rival Companies which have "arrangements" with M. Philippart. We shall be much mistaken if this mysterious transaction turns out well for the parties interested. The era of concessionary electrical schemes is past, and will not be revived again in our time.

ELECTRIC LIGHTING MEMORANDA.

There is a strong rivalry everywhere between the Brush and Edison factions, each side being active in disparaging the other. The rivals may be further described as comprising on the one side the distributors of intense currents, and, on the other, the partisans of currents of low intensity. Thus it is curiously lamentable experience on many occasions that the Brush current is destructive to human life, and is also able to cause damage to property. On the other hand, it is the special boast of the Edison people that a man might, without much harm, grasp with bare hands the two wires connected with an Edison dynamo. In the streets of New York, where both systems are to be found in a few localities, the Edison leads are underground, while the Brush wires are strung overhead. A short time since there was a leak from the Edison cable, and the electricity was led by some circuit by stepping upon both the metals at once. The state of affairs here described was first made manifest to the public by the eccentric behaviour of a number of horses, which were soon gathered opposite the "great horse-exhilarating station," as a newspaper report terms the spot in question; and before long the cause of the mysterious display was discovered. Lucidity to harm was done; but the Edison Company had a fine opportunity for pointing out that if the Brush current had taken a similar course, every animal, instead of being merely frightened, would have been killed on the spot. It happened that a workman employed by the Brush Company was killed about this time by touching the wires attached to a lamp; and the public mind is somewhat distrustful of the system in consequence. Mr. Edison says that all such wires should be buried out of harm's way; but this appears to be what he has not been able to do with his own leads. It is therefore a question how intense currents can be insulated so as to combine with safety, taking due account of the factor of carelessness and blundering.

Some very peculiar business is at present going on between the Faure Electric Accumulator Company and M. Philippart, their promoter or patron. This individual and his friends hold the controlling interest in the Company, and he also has "an arrangement" with another Company, who, it is stated, own the only accumulator fit to compete with the Faure battery. M. Philippart has now ordered that the Faure Company shall cease to exist as an industrial concern—a decision which they had obtained at great cost from the parent Company, which he did not think was worth much, as "electric lighting is now in rather low water." All of the Devon and Cornwall Company was fain to admit that their business receipts up to the present time amount to the small sum of 200 10s. and no more. After this, who should deny that Brush lighting is a paying business?

In connection with the present scare among Brush Companies, it may be noted that a strong point with the petitioning shareholders is the misrepresentation of the Company's position in the matter of the licences for the Lane-Fox lamp. All these concessionary Companies, which are now in such a bad way, were started in business with a stock-in-trade consisting of a guaranteed connection between British and Lane-Fox lamps. Unfortunately, the word *exclusive* was inserted in the prospectuses with reference to both systems, whereas there existed an assignment to the British Electric Light Company of the precious Lane-Fox patent. It now remains for the Court to say whether this blunder, which is now admitted by the incriminated Boards, amounts to a false pretence or not. It is curious to note that the excuse proffered by the respective Chairmen, the evidence of a previous agreement as to what they should say. Every man declared in effect that the mistake was of no importance, because the supposed right to the Lane-Fox lamps is not worth the smallest coin of the realm to anybody. Thus the ingenious inventor's (?) fame is sacrificed upon the altar of expediency. Mr. Lane-Fox has now a good opportunity for soothing his wounded vanity by asking these gentlemen to show what value the other part of their concessions possesses.

An exciting discussion took place at the special meeting

of the Sheffield Town Council last Wednesday, when the desirability of applying for an Electric Lighting Order was considered. In the event, the proposal to apply for an Order was carried by the casting vote of the Mayor, who qualified his action by observing that it was prompted by deliberate opposition to three prominent shareholders of the Sheffield United Gas Company, who voted the other way. This was not a very worthy speech of a judicial functionary, since it seems to imply the preponderance of private over public interest on the part of gentlemen who probably serve the public as faithfully in two capacities as his Worship does in his own temporary office. The amendment which so nearly ousted the original motion was substantially the same as the proposal recently adopted by the Birmingham Town Council; and the debate was marked by all the confusion and misapprehensions which the Electric Lighting Act has so well succeeded in fostering. It is not easy, in discussions of this character, to say which side numbers the friends or enemies of gas and electricity respectively. Everything is in confusion, none knowing what to advise. The only thing perfectly certain is that the ratepayers will have to foot the consulting fee expenses, whether their representatives apply for an Order or whether they prepare to pose as discriminating opponents in the mere spectators.

The Corporation of Chesterfield, whose experience of electric lighting is exceptional, mean to apply for a license from the Board of Trade, avowedly for the purpose of keeping speculators out of the town. From the remarks of Alderman Wood, at a recent meeting of the Town Council, it appears that the Hammond Company have expended from £5000 to £6000 upon the 22 arc and 100 incandescent lamps with which they are supposed to light the town, notwithstanding the fact that the work was done in the cheapest and ugliest manner, are "absolute commercial failures." Whom is the puzzled The Watch Committee have not yet decided that the lighting is a success, and therefore it is impossible to say how long the present experiment may last, since the year's contract is for only to begin from the time when the lighting is accepted as satisfactory. It would not be polite for the Council to declare their intention of forcing out the Hammond Company at the earliest possible moment; but it is not difficult, easy, and respect with other purveyors of electric light, to read between the lines of their decision to invoke the authority of the Board of Trade.

ELECTRIC LIGHTING MEMORANDA.

There has been very little stirring in matters electrical during the past week, the principal event having been the meeting of the Electrical Power Storage Company on Wednesday. The Chairman committed himself to the statement that the prospects of the Company are "of an assuring and flattering character," and the debate was marked by "ing chamester"—an assertion supported by reference to the performances of the inamear, mentioned in these columns last week, and to other notable successes. The meeting seems to have gone as harmoniously as might be expected when, out of a nominal profit of £216,359, not a penny of dividend is available. Our caustic financial contemporary The gas-barrens are, of course, carefully kept in readiness to be turned on in case of the expected breakdown of the new system. The appearance of the rooms by the new light is scarcely so good as before, since the lamps are hung much lower than the old burners, and consequently the decorated ceilings and upper portions of the walls are not so well lighted out. Still, if we must be sacrificed, we must be sacrificed to make some sacrifices.

The gentlemen who now constitute the directorate of the Electrical Storeage Company formed under the patronage of M. Simon Philippart must sincerely regret the incompetence of the Belgian Government in procuring the arrest of Philippart in Paris, virtually on the ground of his being a defaulting bankrupt. M. Philippart came to grief in 1878 amid circumstances sufficiently notorious at the time; and after this event he remained in obscurity until he again burst upon the financial firmament as the promoter of the French storage battery scheme of electric lighting. An affiliated Company was soon afterwards formed in London, and not long ago this same M. Philippart managed to drive out the independent element from the English Board, and reconstruct the Company in accordance with his own elevated ideas. Part of his object in doing this was to effect a combination of all the storage battery interests into one Faure-Sellon-Volckmar constellation. Everything appeared to be going on very well with M. Philippart again—as well, indeed, that certain of his old Belgian creditors thought they should like to share in this prosperity. Other unsecured claimants were lodged with the Brussels authorities respecting M. Philippart's effectuous to discharge his old obligations, with the result already told. By a "simple combination few could ever have reckoned upon," the great financier was arrested, bail being refused, on the same evening when he was to have presided at the inauguration of the lighting by Swan lamps, fed by Faure accumulators, of Pigeon's restaurant in the Avenue de l'Opéra. We are told that the victim of his relentless creditors was surprised and "considerably annoyed" at this treatment. The Parisian police are manifestly too unscientific for this "accumulating" age. Possibly before M. Philippart is at liberty to preside over another gathering of electricians, he will have been taught something about "induction" as well as of "storage."

It seems but as yesterday that Mr. Gray, M.P., and his friends were preparing to set the Liffey on fire, or better, by the aid of the Dublin Electric Light Company, which was to unfold the blessings of Brush lighting to the benighted population of the Irish capital. Never was a greater outcry made concerning a very small matter; and seldom have the mutual congratulations of sanguine speculators been more swiftly and entirely silenced. Before us to-day lies the notice of sale of all the property and effects of the Company, with the doleful inscription, "In Liquidation." Everything, from the license to use the Brush patents, which cost more pounds than it will fetch pence, down to the worn-out fire-bars, is offered for sale by tender on the 14th inst. If not then sold, the whole will probably be knocked down at auction. The liquidator announces that the concern is still "going," and that any one with sufficient capital will find a "large field for successful enterprise" open to him. Meanwhile, what of the capital of the Company?

ELECTRIC LIGHTING MEMORANDA.

Electric lighting companies must still be content to live by their losses, if we may believe a great many reports, concerning which there is little room for doubt. Nobody knows in the City of London; the Hammond enterprises at Chesterfield is notoriously a costly advertisement; and the Edison undertaking in the Holborn Viaduct can scarcely be otherwise regarded. And the same character is ascribed to the last undertaking of the Edison Company in connection with the experimental lighting of the library and smoking-room of the House of Commons. This installation, consisting of 258 lamps of the usual type, was started in working on Monday last week with a fair measure of success, according to various accounts, although the amount of light afforded is not thought to be sufficient. It has been stated that the cost of this experiment to the country will not, in the first place, exceed £800; but that the work has cost the Company more than £2000. Thus the electricians will again pay for their advantage. to be turned on in case of the expected breakdown of the new system. The appearance of the rooms by the new light is scarcely so good as before, since the lamps are hung much lower than the old burners, and consequently the decorated ceilings and upper portions of the walls are not so well lighted out. Still, if we must be sacrificed, we must be sacrificed to make some sacrifices.

The gentlemen who now constitute the directorate of the Electrical Storeage Company formed under the patronage of M. Simon Philippart must sincerely regret the incompetence of the Belgian Government in procuring the arrest of Philippart in Paris, virtually on the ground of his being a defaulting bankrupt. M. Philippart came to grief in 1878 amid circumstances sufficiently notorious at the time; and after this event he remained in obscurity until he again burst upon the financial firmament as the promoter of the French storage battery scheme of electric lighting. An affiliated Company was soon afterwards formed in London, and not long ago this same M. Philippart managed to drive out the independent element from the English Board, and reconstruct the Company in accordance with his own elevated ideas. Part of his object in doing this was to effect a combination of all the storage battery interests into one Faure-Sellon-Volckmar constellation. Everything appeared to be going on very well with M. Philippart again—as well, indeed, that certain of his old Belgian creditors thought they should like to share in this prosperity. Other unsecured claimants were lodged with the Brussels authorities respecting M. Philippart's effectuous to discharge his old obligations, with the result already told. By a "simple combination few could ever have reckoned upon," the great financier was arrested, bail being refused, on the same evening when he was to have presided at the inauguration of the lighting by Swan lamps, fed by Faure accumulators, of Pigeon's restaurant in the Avenue de l'Opéra. We are told that the victim of his relentless creditors was surprised and "considerably annoyed" at this treatment. The Parisian police are manifestly too unscientific for this "accumulating" age. Possibly before M. Philippart is at liberty to preside over another gathering of electricians, he will have been taught something about "induction" as well as of "storage."

It seems but as yesterday that Mr. Gray, M.P., and his friends were preparing to set the Liffey on fire, or better, by the aid of the Dublin Electric Light Company, which was to unfold the blessings of Brush lighting to the benighted population of the Irish capital. Never was a greater outcry made concerning a very small matter; and seldom have the mutual congratulations of sanguine speculators been more swiftly and entirely silenced. Before us to-day lies the notice of sale of all the property and effects of the Company, with the doleful inscription, "In Liquidation." Everything, from the license to use the Brush patents, which cost more pounds than it will fetch pence, down to the worn-out fire-bars, is offered for sale by tender on the 14th inst. If not then sold, the whole will probably be knocked down at auction. The liquidator announces that the concern is still "going," and that any one with sufficient capital will find a "large field for successful enterprise" open to him. Meanwhile, what of the capital of the Company?

MORE ELECTRIC LIGHTING ACCIDENTS IN NEW YORK.

The New York Sun of the 18th of February gives an account of "two more explosions" which occurred at 121, Front Street, in that city, on the previous Saturday morning. It appears that the first floor of the building in question is lighted by the Edison Company, while the other portion is lighted by gas in the usual way. The gas was supplied through an ordinary 1-inch service-pipe (not a 2-inch pipe, as stated in the newspaper); the electric wires themselves being also laid in a pipe, but of smaller calibre and size—as not informed. Both pipes passed into the building under the steps, within a few inches of each other. Overhead, in the basement hall, was the electric meter; and although we were nothing about a gas-pipe being near at hand, the gas-pipe, which follows, this hall, both pipes were in close proximity here as well as under the steps. At the time of the first explosion a man was employed in the electric wires was the first to burst. The fracture occurred at the angle where the gas-pipe turned to enter the building: "and immediately afterwards," we are told, "the meter exploded." An *employé* of the Edison Company was sent for and he could not account for the explosion; but through the rest of the day had something to do with it. The report goes on to state that two different explosions afterwards occurred: the water-pipes leaking in the gas-pipe, set the gas on fire, and set fire to the gas-pipe. As shown of fire was extinguished. The explosion of the electric company cut off the electric wires at either end of the tunnel, and the gas-pipe was plugged up. Mr. Edison ordered an investigation to be made, and republished the idea of the electric meter exploding, he was misinformed. Assessments as it contained nothing explosive, but remarked that when the wires were replaced they would not be carried through the gas-pipe. They had, he said, "been by experience that it was best to keep the wires away from other metals." This looks like a further display of danger, though not chiefly expected.

The latest and most written information dated the 13th inst.) in regard to the occurrences; and also a cutting from a newspaper, which looks like a resuscitation of the whole affair. It reads thus: "Superintendent Chimmond, of the Edison Electric Light Company, reports that the explosions at 121, Front Street, were caused by the rubbing off of the insulating material on one of the electric wires. A spark was created, and soon heated the neighbouring wires, which burnt the electric service-pipe. Escaping gas from a gas service-pipe took fire, and the electric fluid ignited the second explosion." This is very clear, and gives the gas a good half share in the business; but I should like to know Mr. Chimmond's reasons for his becoming deceived of the "insulating material" by rubbing, while lying quietly in a pipe; and how will he prevent such an occurrence in future? If the defect in the lead has caused at the time of putting it into the pipe, what has so lately occasioned it would have happened at starting. Should not Mr. Chimmond rather be on the look-out for the explosions, or whatever took place, were due to the burning of the "insulating material"? Your readers will be inclined to think so, when they come to consider the condition the gas-pipe was found in, or a part of it, and read the last of the investigation took place about, or some little time before the explosions and the firing of the gas, as reported in the *Sun*.

Although we only read in print of the doings of Mr. Edison and his explosive, now that the gas-pipe was plugged, there representing the New York Gas Company were not asleep; for I happen to know that the gas-pipe was carefully examined, and, to the astonishment of all concerned, three large holes (for its size—1 inch) were found in it near where the electric defect was found to be, each hole indicating clearly that it had been formed by the *fusion* of the iron, not lead. Does not this show us why Mr. Edison has determined "to keep the wires away from other metals" in future? The perforated pipe is in the possession of the Gas Company.

W. H.

June 30, 1883.

ELECTRIC LIGHTING MEMORANDA.

Since the matter was last mentioned in these columns, the Chairman and other Directors of the Commissioners of Sewers of the City of London have been far as may be gleaned from the report of the proceedings, busily debating the question of electric lighting. The strange the principal, if not the only business done during the year manner in which the Special Committee have dealt with the has been to maintain 31 lamps at Middlesbrough. Cannon references left in their hands during the past nine months Ina Street is in Middlesex; yet it was the concern of the York- evidently caused deep dissatisfaction among the rest of the shire Brush Company that was being discussed. The Direc- Commissioners; and it will scarcely be surprising if the whole tors claimed that the working referred to was profitable, arrangement is altered once more before anything is done. It is becoming evident to the Commissioners—as it has always been to observers of their proceedings—that their scheme of source, of less than £900 per annum, will maintain offices keeping the property in themselves, yet quitting the actual work and staff in London as well as works in Yorkshire. The not more. At a recent meeting of the Court, one of the with one another. Thus the Yorkshire Brush is about to be members wished to put to the City Solicitor a series of ques- tions which would have brought this particular point into a strong relief. Unfortunately for the purpose of the ques- tioner, he so framed his inquiry that a negative answer to the first of them quashed the remainder. It was desired to know whether the contracts must be made before the Provisional Order or Licence could be obtained; and then if the grant of the Order would release the Gas Company from their responsibility. It should have been earlier per- ceived that a negative reply could easily be made to the first question, which was the case; whereupon the others were ruled as being out of order. This is regrettable, because the information would have been equally valuable on the supposi- tion that the contracts were to be made after the Order had been obtained as under the opposite condition. It is the opinion of many competent persons that, in any circum- stances, the Electric Lighting Act would enable the Chartered Gas Company to put the City authorities in a fair stroke so soon as the new light became commercially successful in a given district. Whether the Gas Company will stand upon their rights in this unpleasant manner need not now be discussed, as the preliminary conditions are still purely imaginary; but their action would not be affected in the slightest degree by the circumstance of the competing light being introduced by the authorities or by semi-independent contractors. This is the point upon which the City Solicitor should have been heard. It was felt, however, that a strong opinion on the point must damage the Commissioner; and so the matter was dropped, and the doubt hushed for a time.

While dealing with the proceedings of the City authorities, it should be observed that the Sewers' Committee have failed to obtain from the electrical supply companies with whom they have been treating, anything like a comprehensive or satisfactory tender. There are only two offers left to be finally considered; and one of these does not bear the stamp of seriousness. The Edison Company are willing to continue their present show, on compulsory terms, charging for the public lamps the rate now paid for gas. There is not much information in this statement. The Gilchrist Company pro- pose to light the thoroughfare from Bishopsgate to Aldgate High Street for 25s. per quarter for every 20-candle power "nominal" lamp. Private consumers are to be charged 8½d. and 6d. per commercial unit, respectively, by the two contractors. This is the basis upon which the Commissioners are now asked to apply for a Licence; but it is doubtful whether such a step will be taken, in view of the vague but positive responsibilities attending the possession of such powers. It is somewhat curious that whereas, when they were last heard from, the Committee wanted to spend £200 in experiments, they can now publish information, such as it is, upon which they profess to be ready to go before the Board of Trade. The whole affair is a sham from beginning to end. The Committee evidently wish to be relieved of their duties, and would be much obliged to everybody if their reports and opinions could be quietly lost sight of, and as quickly as possible forgotten.

Another Brush Company have not to hear more or less apologetic speeches from the Chairman and other Directors. The meeting was held at the Cannon Street Hotel; and, as usual, was of a somewhat stormy character, as may be understood from the fact that the report and accounts were not adopted.

Now that the dead season has fairly begun, some of our electrical and engineering contemporaries are amusing their readers with the discussion of a proposal by M. Gaulard to light the Suez Canal by electricity. It is not needful to explain how the work was to be done, since the author of the scheme estimated the cost of the complete installation at something less than £100,000; while one of his critics (equally qualified to deal with these matters) contends that the cost of the leading conductors alone would be £940,000. The disputants are still hammering each other with volts, ohms, and other deadly weapons of electrical controversy; while the Philistines stand apart and smile. After this further evidence of the certainty of modern electrical science, who shall doubt the truth of the well-worn saying, that electric lighting has passed the era of experiment, and entered that of commercial fact and experience?

ELECTRIC LIGHTING MEMORANDA.

As time goes on, the position of the Board of Trade with regard to electric lighting appears to grow worse and worse. It will be remembered that when the Electric Lighting Act was drafted, it was recommended as a notable departure from all established practice, inasmuch as it sought to deal before, rather than after, the event. It was supposed that in this way the growth of those dreadful vested interests which the gas and water companies had succeeded in creating for themselves, would be prevented; and the path made straight for the eventual requisition of all electrical undertakings by the community. From the experience thus far acquired of the working of the Act, it may almost be thought that the Board of Trade will themselves soon begin to wish they had not been in such a hurry; but had waited until everybody knew what was needful in the way of legislation. Of all the criticisms of the Act, and the proceedings of the Board of Trade under its powers that have yet appeared, the sharpest is that emanating from Mr. T. H. Blakesley, M.A., recently published in pamphlet form by Sampson Low and Co. Some Mr. Blakesley's observations are warmly taken up by the *Engineer*; especially those whereby it is shown that the Board of Trade rules are mostly in favour of the consumer against the consumer. We do not now speak of the questionable way in which the Department has turned to account the Orders on the first comers; for upon this there are numerous mistakes which Mr. Blakesley points out in the drafting of the Orders. Thus it is said the clauses enjoining electrical companies to supply every street within their compulsory district, are so loosely drawn that the companies are only required to lay their wires in a street, but not through it new along it. Consequently, a distributing box laid under the pavement at the beginning of a street, would, in law, be held to serve the King's Road, Chelsea, which, according or the only thing on this earth that never comes to an end. Another important matter is that any Electric Lighting Company may supply intermittent currents if they so choose. These currents are useless for driving motor machinery, or charging secondary batteries; and are, moreover, very dan- gerous to life. If we remember aright, Mr. Monkton is partly responsible for this, for he induced the Parliamentary Com- mittee to believe that there was no such thing as a good or bad current; all supplies of electro-motive force being as simple of application as so much gas or water. On the whole, the *Engineer*, in regarding the present technical and legislative condition of matters electrical, anticipates a period of confusion and turmoil in the autumn and winter, which will, on the one hand, tell against the progress of electric lighting, while on the other it will be a disgrace to the Board of Trade.

The Annual Report of the Grosvenor Electric Light Company has been issued, and as might be expected, has been criticised by our financial contemporary, *Money*. There will be a huge post-mortem inquiry before long upon all these companies; but meanwhile it is to be hoped that the Directors of all such anæmic enterprises are possessed of sufficient insensibility to patiently endure the sacrificing which they receive. The Grosvenor Company is that which has received the support of Professor Crookes, who gave them (for a consideration) the form of incandescent lamps invented by himself expressly with a view to avoid the defects of all previously existing models. Even with these advantages, however, the Com- pany appear to have lost £18,878 on their first fourteen months' working; and to have thereby shown that the patents which are valued in the accounts at £198,779 can scarcely be worth anything at all. Our contemporary has a rough-and-ready way of estimating the value of patent rights; for it, it says, the possession of a patent brings the owners of it to lose so many thousands of pounds a year, what can be the value of the patent? Certainly not what was paid for it on the assumption that it would return a profit. The meeting of the Company was held on the 28th ult., and was of a somewhat stormy character, as may be

ELECTRIC LIGHTING MEMORANDA.

Nor much is heard as yet of the Electrical Exhibition at Vienna, for very obvious reasons. It was opened with sound and state on the 16th inst., by the Crown Prince; but it was not naturally in a very unfinished condition. It has been said that the English sections practically did not exist on the opening day, except as an excuse for the appearance on the scene of Lord Stanley, Sir Frederic Abel, and Sir William Siemens, in their ornamental British Commissioner. The English Government did not support the undertaking very liberally for combination being limited to £500. This is quite enough, under the circumstances; for the Austrians, in holding their exhibition at this time, are "a day after the fair." Very few English exhibitors of electrical machinery, especially in connection with lighting, can now afford to throw away much money in showing their goods without immediate prospect of selling them. There may possibly be an unoccupied field for company promoters in the East of Europe; but as everybody with capital in Vienna must be fully aware of the state of the electrical share market in England, the chances for making an indirect profit out of the present opportunity for advertising must be slight.

The financial condition of the Pilsen-Joel and General Electric Light Company is ruthlessly exposed in the current number of *Money*. The Company have now been working for thirteen months with a capital of £25,925. On the first year's revenue account there is an admitted loss of £7152, but the Directors—who have received £1160 by way of fees for conducting the affairs of the concern to this pass—find the results of their operations "by no means discouraging." Of course the Directors are in negotiation for some important public contracts—the managers of these undertakings are all wonderful negotiators—but it seems that another call of 10s. per share has become necessary. Under these circumstances, our contemporary kindly prepares a balance-sheet, showing what is termed the position of the Company after the elimination of "bogus assets," such as goodwill and patent rights; and by this statement the concern stands with a deficiency of £90,511. This is pretty well for one year's operations. The shares of the Company are stated to be worth 2s. 6d. less than nothing: that is, would-be sellers must give half-a-crown with every share, in order to get rid of it.

As might have been expected, the recent declaration of the Board of Trade against electrical licences for speculative companies has awakened many strong protests, from people—multitude of granting permission for electrical undertakings included in the General Act—Provisional Orders and Licences—the Board would have a preference for the latter, as being their own special invention for the occasion. Of course the restriction of Licences for large areas to local authorities was an afterthought; but, even so, it is not by any means clear that electrical supply companies are justified in regarding it as a further limitation of their rights. There is much reason in what the Board of Trade now say about the duration of a Licence being too short for the repayment of the undertakers; and it will be remembered that this was one of the strongest points urged on behalf of the Electrical Companies before Mr. Stanhope's Committee. It was solely for that benefit that the duration of Provisional Orders was extended to 21 years, upon Sir J. Lubbock's representation. And yet now, the electricians turn round and complain because they are debarred from obtaining the shorter term which they originally condemned. They ask why, if they succeed in securing the consent of a local authority—the only previously-known preliminary to the grant of a Licence—they should be driven to the expense of seeking an Order. If they have as much experience as Gas Companies have of the feebleness of local authorities, and really mean business, they would regard the temporary favour of the latter—not as a reason for trusting to it for six years, but as an assurance that the time was favourable for going to the Board of Trade for an Order. It is possible, however, to believe that all these complaints are honestly founded.

From copies of the *Melbourne Argus* just to hand, it appears that the Edison lighting of the Assembly and Legislative Council Chambers repeats in Australia vagaries in which it occasionally indulges in England. What is described as "mild" by the result of short-circuiting two of the lamps. "In each case there was a noise resembling that produced by a rocket, and an infinite heat was produced which melted the brass brackets. The molten metal, dropping on the cushioned seats, burned them slightly." Fortunately the lamps had been, and further damage was prevented by the prompt action of the officials. On the same evening the numerous than the one quoted above, but not more plainly based on truth or experience. Indeed, it was scarcely worth while to say anything by way of explaining the course that has been followed through necessity. If the shareholders of the miscellaneous Brush Companies were not previously united in interest, there was a wonderful confusion of Directors; for it is reported that the Chairman of Hammond, who spoke as Managing Director of the Company which bears his name, had just previously presided over the Birmingham and Warwickshire Company's meeting. It must be consoling to these gentlemen to know that nobody is likely to interfere with their friendly little schemes of amalgamation, as in the similar proceedings of Metropolitan Gas Companies. At least, if the Board of Trade should eventually take any interest in the matter, it will probably be handled by a branch of the Department which will be constituted for fresh business at the beginning of next year.

It is reported that the Alliance and Dublin Consumers' Gas Company have bought, for £10000, the plant of the defunct Dublin Brush Electric Light Company. What amount of truth there may be in this statement we do not know; but, if true, it is at least to be hoped that the Gas Company do not intend to take the enterprise that brought the Brush speculators to grief. The news is a striking comment on the pretensions of these latter, who made a market of a "concession," which they had obtained for a song, to a Provincial Company, and raised a considerable sum of money, a large proportion of which was spent upon plant and tools. Now we are told that all this grand venture, concession, plant, goodwill, and all the hopes of the Brush interest, have been delivered up to the local Gas Company for the ridiculously small sum of £10000! The latter have during the past year or two kept up a fair electric lamp in ventilation of the permission granted to them in their Act of 1859 to supply gas, and other improved means of lighting. It is perhaps as well to keep this particular enactment from lapsing, so long as the capital applicable under the same Act remains available; and the Company may have private reasons for adopting their present course. Notwithstanding all this, however, on general grounds it is regrettable to see a prosperous Gas Company tampering with electric lighting in this fashion.

Electricians are their own foes in one thing—the ill-luck that constantly attends their efforts to achieve special success on "show" occasions. Whenever their services are required for a great banquet, or a great evening party, the electric lights are in favour of something going wrong just at a critical moment. This was the case at the Guildhall on the evening of the Lord Mayor's banquet. In one newspaper only—*Lloyd's*—worthy of mention for its disinterested confession of the truth, it is stated that in the middle of the presentation of the distinguished visitors "the electric light immediately," over the dais flickered and disappeared, leaving the gorgeous "group in comparative shadow."

A statement of the actual cost of the electric lighting of the London Road Station, Manchester, has been published; and the figures are in marked contrast with the fanciful estimates of electricians. The annual gas bill of the station formerly

ELECTRIC LIGHTING MEMORANDA.

THE amalgamations of Electric Lighting Companies, to which reference has already been made in these columns, was agreed to on the 12th inst.; and henceforward the Yorkshire Brush, the Birmingham and Warwickshire Brush, and Formanit Company. The circumstances of the amalgamations are sufficiently out of the ordinary to call for some comment. Mr. Robert Hammond on the occasion. This individual is reported to have let leakers that the public are "anxious to have the electric light"—the chief evidences of which is talking to amalgamations as an alternative to winding up. This reminder of Mr. Hammond's observations are less based on truth or experience. Indeed, it was scarcely worth while to say anything by way of explaining the course that has been followed through necessity. If the shareholders of the miscellaneous Brush Companies were not previously united in interest, there was a wonderful confusion of Directors; for it is reported that the Chairman of Hammond, who spoke as Managing Director of the Company which bears his name, had just previously presided over the Birmingham and Warwickshire Company's meeting. It must be consoling to these gentlemen to know that nobody is likely to interfere with their friendly little schemes of amalgamation, as in the similar proceedings of Metropolitan Gas Companies. At least, if the Board of Trade should eventually take any interest in the matter, it will probably be handled by a branch of the Department which will be constituted for fresh business at the beginning of next year.

It is reported that the Alliance and Dublin Consumers' Gas Company have bought, for £10000, the plant of the defunct Dublin Brush Electric Light Company. What amount of truth there may be in this statement we do not know; but, if true, it is at least to be hoped that the Gas Company do not intend to take the enterprise that brought the Brush speculators to grief. The news is a striking comment on the pretensions of these latter, who made a market of a "concession," which they had obtained for a song, to a Provincial Company, and raised a considerable sum of money, a large proportion of which was spent upon plant and tools. Now we are told that all this grand venture, concession, plant, goodwill, and all the hopes of the Brush interest, have been delivered up to the local Gas Company for the ridiculously small sum of £10000! The latter have during the past year or two kept up a fair electric lamp in ventilation of the permission granted to them in their Act of 1859 to supply gas, and other improved means of lighting. It is perhaps as well to keep this particular enactment from lapsing, so long as the capital applicable under the same Act remains available; and the Company may have private reasons for adopting their present course. Notwithstanding all this, however, on general grounds it is regrettable to see a prosperous Gas Company tampering with electric lighting in this fashion.

Electricians are their own foes in one thing—the ill-luck that constantly attends their efforts to achieve special success on "show" occasions. Whenever their services are required for a great banquet, or a great evening party, the electric lights are in favour of something going wrong just at a critical moment. This was the case at the Guildhall on the evening of the Lord Mayor's banquet. In one newspaper only—*Lloyd's*—worthy of mention for its disinterested confession of the truth, it is stated that in the middle of the presentation of the distinguished visitors "the electric light immediately," over the dais flickered and disappeared, leaving the gorgeous "group in comparative shadow."

A statement of the actual cost of the electric lighting of the London Road Station, Manchester, has been published; and the figures are in marked contrast with the fanciful estimates of electricians. The annual gas bill of the station formerly averaged £174; and the outlay for light was then controlled by economical considerations. By doubling the expense for gas, the station could have been brilliantly lighted; but this was not thought of. Electric lighting was introduced; the annual coating £2481, in the first place, while the annual expense, including depreciation, is no less than £626. In four years, then, increasing the total cost of lighting the station to £7447, or about 4¼ times the average previous cost of gas. It is admitted, moreover, that the electric lamps have "sometimes failed unfavourably when trains have been entering the station;" although, in fairness, it should be added that the light is now deemed so reliable that the gas-brackets still remains—the miscellaneous of the 22 lamps. Now lamps are being got ready, however, which will further swell the capital account; but, it is hoped, will remove the last objection. Comment on these figures is superfluous.

ELECTRIC LIGHTING IN NEW YORK CITY.

[FROM OUR AMERICAN CORRESPONDENT.]

A reader of the JOURNAL writes to inquire what is the information in regard to the progress made by the electric light in New York City, about which I have treated of at different times in my "Notes." I fear that I cannot gratify his request. The truth is that there is very little information which they do not possess. City is the same as in other municipalities, when the electric light is the rule per lamp was put down very low, and the gas-burner introduced was a very poor one. Then as soon as we had it, others followed suit. This was a weight that was soon expected; for the light was a novelty, and so was quickly appreciated by the general public.

In the matter of street lighting, last year the Company took out the equivalent of 47 lamps. I say equivalent, for in two instances—there are 6 lamps at the top of a high mast; these 6 lamps are reckoned as being equal to 25 ordinary lamps, or, in other words, are supposed to give 150 lights. This calculation has been altered for the present year, the Brush Company have been cut down in this respect; the Superintendent of Lamps claiming that these 6 lamps are only equal lighted by 12 of the street lights, thus they are at present for 300 lamps. So these lamps are now figured as being equal to 12 lamps in number. In addition to the above, two masted lights on Brush system, of 30 each, will soon be in use for the public lighting. These are to be worked from the Fifth Avenue Station, and will be the first use of the electric light used for street lighting. The price charged for city for these lamps is 70 cents per lamp per night, or 350 dols. 50 c. a year. The lamps are reckoned at 2000 candle power, the Brush Company calculating by French measurement; while the United States Company's are supposed to be of 2000 candles power by their nominal tests. Each of the latter lamps is of 9 amperes, 2½ volts, burning 3 feet an hour, while 450 arc street lamps will be required to be supplied with 10 amperes. These gas lamps put out by the new illuminant—an insignificant figure when it is remembered that there were about 21,000 street lamps in use prior to the introduction of the electric light.

When we come to compare the cost of the two systems of lighting, the following statistics will be interesting. The cost of gas per lamp per night, as charged by the Company, is 10 dols. 50 c. per annum, or 10 dols. 50 c. 365 nights = 3832 dols. 50 c. These were replaced by electric lights, reckoning as a basis of one of the latter to seven gas lamps, because would be 547.357 dols. It is thus clear that the cost of the electric light must be greatly reduced before it supplants gas for street lighting.

For private lighting a similar state of things prevails; that is, the electric light is employed for the lighting of stores, offices, and some of the large quality of gas used. They are chiefly used in stores, warehouses, and similar places; and the principal purpose here is for advertising, rather than for lighting. I shall not be far out if I place the total number of electric lights in use in New York City as 1500, which includes public and private lights. The large lights of 2000-candle power when used for private lighting, are usually charged for at the rate of, 1 dol. per night, or 365 dols. per annum per lamp.

No practical work has yet been done here with the incandescent light. The Edisonian scheme for lighting the lower part of the city still drags. How it is promised that everything will be ready by the fall.

Finally, I have yet to learn of a single instance where the gas-meter has been removed for the electric light.

ELECTRIC LIGHTING MEMORANDA.

The fashion of amalgamation is making further headway among electricians; for it is announced that the Diamond Company are about to annex not only the Yorkshire Brush, but the Birmingham and Warwickshire Brush and the Ferranti Companies. It is curious to reflect that, only a few months ago, there was supposed to be such a wonderful business in electric lighting, that every English county—not to say nothing of foreign lands and distant colonies—was thought to require a separate Company for providing one particular system of lighting. Now the contrary opinion prevails, and it is found expedient to consolidate; for experience shows that both work and profit are scarce, even when concentrated in few establishments. We are not sorry all concerned here to reconcile this fact with the supposed continual progress of electric lighting; but the truth remains as a sign of the times, whatever interpretations may be given to it. After all these family arrangements have been concluded among the Brush offspring, it would be a neat way of completing the process of re-absorption if they were to go back to their parent, the original "Anglo-American Brush Corporation. And even if this concern should afterwards retire across the Atlantic, to the native land of all the Brushes, and drops its much-abused prefix, the corpse of electric lighting in Great Britain would not materially suffer.

Writing of the Brush system, we are reminded that the lighting in the district of Ludgate Hill and Blackfriars, London, was very unsatisfactory during the past week. The particulars have given elsewhere; but it is enough, to show the serious nature of the difficulty, to state that the Brush lamps in this important district could not be lighted at all on Monday night, and for several successive nights they were out at intervals. The gaslamps were brought into use nights after night to supply the deficiency; and last for this timely aid, the consequences would have been very serious. The Police and City authorities were naturally concerned; for it is no small trouble to have the streets plunged in darkness at the busiest period of the evening, when the shops are being closed, and the thoroughfares are choked with passengers hurrying to all points of the compass. It is nearly time that the miserable farce was stopped, and the danger of a grave disaster removed. It has been abundantly proved that it is the presence of gas that protects the Electric Lighting Companies in carrying out their advertising. The Gaslights and Coke Company, the Brush Company (and the Edison experiment too) would long ago have been driven out of the City.

The Edison Company have also been in trouble in New York, according to the newspapers; and great inconvenience has been caused to the subscribers by a general breakdown of the supply. To give the Company due credit, they seem to have been doing their work as well of late than their customers were wholly unprepared for what has happened. Nobody conversant with the case has been expected by any, of all, electric lighting worthy of being regarded as a commercial system. Electricians, when approached with misfortunes to the limited seals of their operations; and they hoped to set up in the future, similar interruptions of supply could not occur. This excuse has never been accepted by thoughtful observers; and it must stand discredited after the recent New York experiences. From come to hand, it would appear to have been a case of too much rather than too little current; for the safety links of feasible metal attached to all the services were destroyed, These are intended to protect the lives and property of the subscribers against the introduction into their premises of dangerously powerful currents; and the principal satisfaction to the electricians in the present case is probably the evidence that the device acted in the proper manner. Electrical machinery does not invariably answer the purpose expected of it; but those safety links have proved a noble exception. However, whether from excessive pressure or otherwise, the instructive fact remains that Mr. Edison's lights went out with startling suddenness and unanimity, notwithstanding all the care bestowed upon the arrangement and management of the generating and distributing plant, and the daily presence of the inventor himself.

It has been pettishly said in some scientific journals that the owners of the gas industry, at home and abroad, wilfully refuse to acknowledge the advantages and progress of electric lighting; forgetful of the fact that gas lighting was, in its infancy, even more ridiculed and abused than electric lighting is now, even by interested opponents. If the originators of this complaint would take the trouble to peruse our columns during the past year or two, or even to duly appreciate the three preceding paragraphs, they would see that there are two sides to the question even of electric lighting. We surely cannot be blameable for exposing the sides which partisans of the new movement studiously endeavour to conceal from public gaze. Nobody who reads our columns week by week will accuse us of neglecting any available sources of information on this interesting subject. It is not our fault if experience confirms the belief that the shadows of electric lights are very dark indeed, and that the public are often the latter warned against danger by the introduction of a little gaslight among them.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [Nov. 27, 1888.

ELECTRIC LIGHTING MEMORANDA.

It has transpired that the Electrical Exhibition at Vienna has resulted in a very heavy loss; and it is asserted that the guarantors will be required to pay at least half the amounts for which they made themselves liable. This is unfortunate for the Council of Arts as may have entered their names for large sums, under the impression that they would thereby obtain a certain degree of notoriety without incurring any real expense. The result is not surprising to an observer of the West of Europe. Vienna is badly situated for holding exhibitions. It is a very delightful capital—perhaps the most industrial in civilization. All its paying visitors must come from the West; and after these have been surfeited with shows of electrical lamps and machinery at home, they can scarcely be expected to go to the banks of the Danube to see more. Hence the Vienna enterprise has been left almost entirely to the Austrians and their South German neighbours, with disastrous results from the financial point of view. As to the scientific aspect, there is not much to be said. The electricians and their friends claim that great things were demonstrated; and wonderful improvements upon the Paris Exhibition of 1881 shown in the lighting department. Upon this point there is conclusive evidence on the contrary, which has not been mentioned in any of the English newspapers or scientific journals wherein notices of the exhibition have appeared. It has been ascertained that the consumption of mechanical power for a given amount of light has not been lessen was held. As a matter of fact, twice as much coal was consumed in Vienna as in Paris, to produce a given lighting effect; but it is acknowledged that the Austrian coal was greatly inferior to that consumed in France. In the face of this fact, it again becomes evident that the progress of electric lighting, in whatsoever direction it has gone, has not been in the way of economy.

The Metropolitan Railway Company deserve to have their underground stations successfully lighted by electricity; for they have made numerous attempts in this way, but hitherto, without much encouragement. At one station and another, they have set up generating machinery, the working of which filled the ladies' tunnels with an exasperating roar; while the lighting of the platforms was—in certain spots—so dazzling that the drivers and guards (human mothers as they are) could scarcely see the dim signals. One after another these experiments have been abandoned; but now a decided success is announced. The "secondary generating" system of Messrs. Gaulard and Gibbs has been installed at three or four stations. This system consists in sending a powerful alternating current—derived in this case from a Siemens dynamo, driven by a 85-horse power steam-engine—through a closed metallic circuit, upon which insulation coils are placed where required. An induced current is derived at these points; and this supplies the lamps. The idea is a good one, and works well in practice; as shown during the recent Inventions Exhibition at Aquarium. It is said by experts, however, that the induction apparatus costs a great deal of money, and that the loss of conversion is necessarily heavy. This is a matter concerning which nothing definite has yet transpired. It will be a question of comparison between the losses and waste of this and the more direct systems. Nonsee them can boast of cheapness; and if Messrs. Gaulard and Gibbs can see their way indeed in providing a steady and safe light, they will have done great things. Unfortunately, there is no better guarantee against the instantaneous stoppage of the induced than of the primary currents more commonly used.

We do not hear so much now as a few months since about the utilization of natural forces for conversion into electrical energy, to be again transformed into light. The elevated and practical geniuses of the daily newspapers at that time broke into indignant queries why every watercourse did not lady to light all the towns on its banks, and why the tide were still permitted to rise and fall "in vain." Where running streams did not exist, and the sea was also inconveniently distant, the rainfall was to be stored up, or the winds were to yield their strength for the service of lighting lonely villages by night. All this maudlin talk has died away; and the gas steam-engine remains the chief source of mechanical active. Recently, however, the question of gas has benefited the topic afresh, in a momentary departure from its usual calm scene; being apparently stung by the "candescent electric lighting, under the most favourable "conditions, must at present be at least twice to thrice "that of gas." As a remedy for this disastrous state of things, it is asked whether something could not be got out of a windmill, wound up by a windmill, and allowed to fall slowly over a cliff or down a well! The suggestion is made, in a very faint-hearted manner, as indeed it might be; and its appearance in a serious scientific journal merely shows how sore the cull is felt to be, for which such a remedy could be entertained, even as a dream.

The present stagnation in matters electrical has been commented upon in the *Science Monthly*, in an article wherein it is admitted at the outset that "somehow the general sen- "blem of domestic electric light does not seem to advance "much." There is acknowledged to be a steady crop of minor electrical inventions; but the speedy advent of the system of electric lighting or electric locomotion on a large scale is not yet indicated. After admitting this, however, the article proceeds to offer a "crumb of comfort," by pointing out that the electrical world is now subsiding into the normal state; the apparent stagnation being only apparent, and wholly due to the high pitch of excitement in which it has been kept by the rapid succession of startling discoveries within the past few years. All this is very nice and consoling; but it is probable that many people, who have made their money without seeing any hope of its return, will question the statement that the present stoppage is only apparent. It is too real to them; and "when the overcharged "market is purged of its superfluity," and the wonderland returns to prosperity takes place, it will not be the present losers who will participate in it.

ELECTRIC LIGHTING MEMORANDA.

The New York public are becoming seriously alarmed on the subject of the overhead electric light wires that have been strung recklessly over the city by the Brush and other electric light companies. The *New York Times* has been fanning the agitation for the compulsory removal of these wires, which are stated to be altogether 500 miles long. The danger is traceable to this source is threefold. The current conveyed through the wires is sufficiently powerful to strike dead any man who may touch them under certain conditions; the wires have become overloaded, and thus set fire to buildings; and, by interfering with the working of the fire-alarms telegraph, as they have repeatedly done, conflagrations are enabled to get beyond control before any intentions of their breaking out can reach the firemen. Lurid articles, more *Jarndyce*, headed "Wires that Burn and Kill," have appeared in the columns of the above-named newspaper; and the opinions thereupon of various Fire Commissioners, Chief Engineers, and other more or less important members of the Fire Department, have been diligently collected. After perusing these blood-curdling narratives, we are positively relieved to think that in England we enjoy the protection of an Electric Lighting Act. In New York at least one Company never took the trouble to ask anybody's leave to erect their poles and string wires along the streets; but "simply went ahead, and did it at their own sweet will." This would probably be applauded at the time as a display of native "smartness" by the same newspaper writers who now clamour for the removal of the unauthorized wires. To the credit of the Edison Company it should be stated that all their wires are underground.

The reports and statements of accounts of the various concessionary Brush Companies in England are coming out in rapid succession, as they were all originated at about the same epoch of mad speculation, and will probably die off by the same epidemic. The South African Brush Company have lost £6,420 on the year's working, exclusive of parliamentary expenses. The chief business done seems to have been some spot, 49,725*l.* and for which the Company were paid only 22,253*l.* At this rate, as there is some cash in hand, it is estimated that the Company will last a year or two longer. In the columns of *The Times* the reports of the two longer, South-Eastern Brush Companies have appeared together, in a very curious manner. The former confessed a loss of £33,13*l.*, and the latter admitted a loss of £23,31*l.* "Against "this loss, however, is to be set the value of the 29,000 "shares of £1 each in the Consolidated Electric Company, "Limited, which the Directors consider are fully worth their "nominal value," &c. These words are the remainder of the report, and the total in the two cases, excepting only the trifling difference of the figures representing the respective losses. We have often remarked the family feeling that prevails among the Brush companies, but never before observed it in so decided an expression as the issue of identical reports. The Midland Brush Company have also held their ordinary general meeting, and confessed to a loss of 22,29*l.* The Chairman told the proprietors that no more calls would be made, as the Board "had had no means of employing the "money." Finally, as the main result of the meeting, the capital was reduced from 250,000 to 270,500. This does Brush lighting prosper.

In course of time the truth about the recent brilliant display of electric lighting at the Fisheries Exhibition may be told, in disconnected fragments; but it will scarcely appear as a whole. It has been stated that the greater part of the expense in connection with this display was borne by the exhibitors; the Executive Committee paying very little more than praise and complimentsfor the services rendered. It might have been thought that the time had gone for costly advertisements of this order, of which there have been too many, even for the participants, since it is tolerably certain that only the pioneer speculators—such as the original Brush and Edison Companies—have found profit available. Perhaps the fact that the lighting was obtained on such cheap terms, was one of the reasons why so little notice was taken of its occasional failures. At all events, it may be hoped that there will be no more gratuitous lighting of

ELECTRIC LIGHTING MEMORANDA.

Many people will not be very sorry to hear of the return to England of Mr. Edward H. Johnson, of the Edison Electric Light Company. Visitors to the late electrical exhibition at the Crystal Palace, as well as those who happened to meet Mr. Johnson in the committee-room of the House of Commons when he gave evidence on the Electric Lighting Bill, will not readily forget this gentleman's amusing and interesting speeches. During the past winter he has been at work in New York, with Mr. Edison, upon the experimental lighting of some of the lower portions of the city. His first public manifestation since his arrival has been by way of a letter to *The Times*, on the vexed question of electrical measurements and charges. It is indeed high time that Mr. Johnson or some other practical electrician took up this matter, or it would be hopelessly muddled by the swarm of self-styled experts called into "mysterious" existence during the past year or two. Mr. Johnson contends that the only rational system is to charge for light, and not to vex the consumer with the terms in technical use among electricians. The consumer does not, and need not, trouble himself about electrical quantities, since the only effect he can obtain therefrom is the perfectly intelligible one of light. Consequently, upon the Edison system, a subscriber's account is rendered for (say) 48,000 candles of light. This amounts to 48 lamps, all of which are of 16-candle power, and taken note of the number of hours they burn. To finish he has 10 lamps burning 10 hours per day, or 1 lamp for 100 hours. This for 30 days gives 1000 lamp-hours, and multiplied by the Company's standard of 16 candles yields 48,000 candles; and thus, says Mr. Johnson, "he has proof positive "that the bill is correct." The simplicity of this method is unquestionably compared with the manner of measuring gas, the consumer know that every incandescent lamp gives the light of 16 candles? And do they never vary? The idea that sumer in the simplest fallacy, as gas-works officials know full well. If Mr. Johnson had ever been called upon to answer indignant inquiries, "How is it that my gas bill is so much more "than it used to be, when I have not had so many lights?" he would not be so confident in the matter.

Speaking of gas measurement, it should be noticed that Mr. James N. Shoolbred gave a lecture at the Society of Arts on the 4th inst., on the measurement of electricity. This lecture was a good *résumé* of what has been done in this direction, and the subsequent discussion was also instructive. We mention it for the purpose of commenting on a speech of Mr. W. H. Preece, who, for a man who never misses a chance of speaking in public, seldom commits himself. On this occasion, however, he ran a tilt against gas-meters, and in so doing damaged himself more than the objects of his attack. His challenged point was seen in the room to explain the mechanism of a gas-meter and describe its action, and then went on to say that it was a complicated machine in comparison with the apparatus mentioned in the lecture. It is not to be supposed that Mr. Preece does not himself know what a gas-meter is; but if he was speaking of his own ignorance, we might recommend him to visit the Crystal Palace as speedily as possible, and repair his deficiencies in this respect. It might be thought that if the mechanical attainments of his auditory were not equal to the comprehension of an instrument easily made by workmen with no pretensions to scientific culture, they could scarcely attempt the construction of electrical apparatus. It is more charitable to suppose, however, that while electricians know their own tools, they ought to be content to leave gas apparatus to those who understand it. It is scarcely fair to charge a butcher with clumsiness because he cannot handle a fuller's shears. As Mr. Preece and electricians generally are learned men, it will perhaps be more in their taste if we recommend them to bear in mind the old observation, *ne sutor ultra crepidam.*

The electric light has not yet obtained exclusive possession of the Houses of Commons, for the room occupied by the now Grand Committee for Bills relating to Law and Courts of Justice is lighted by sun-burners on Sugg's most improved principle. In addition to lighting the room, the sun-burners also materially assist the ventilation. Even the *Daily News* is fain to confess that this is a triumph of gas lighting, "quite putting in the shade the electric light in the dining-room and library adjoining."

THE EDISON LIGHTING ON THE HOLBORN VIADUCT.

Above is given a full report (to the Streets Committee of the Council, which referred the matter to the Edison Lighting Company) of the electrical lighting of the Holborn Viaduct. In our editorial notice last week, Dec. 4, 1882; and, after having had the lighting was commenced on the 25th of April, lighted on the Edison System, have remained in operation, continuously on the 25th of January of the present year, to continue the experiment until the Corporation were ready for the lighting contract to be entered into for a further term of twelve months from the last-mentioned date, or for such shorter time before the expiry of the present gas lighting should be changed. The Viaduct had been finished, on April 27 last, been lighted for a period of twelve months; and the Edison Company undertook to light it.

After describing at the commencement the period that the report dealt with, the report gives the number of lamps employed in carrying out the lighting, the kinds of lamps there were, the number of lamps in each kind, and the number of hours they were burned. Seven different kinds of lamps were employed, the total number of which was 2,250. Of these, 1,000 were of 8-candle power each, and 20 of 2-candle power each. Two hundred and forty of these lamps were placed in the majority of the ordinary gas lanterns, and were burned during the night hours only. Fifteen lamps were placed in the centre lanterns on the bridge. The lamps on the 6-light cluster lanterns were modified towards the end of August by the substitution of 8-candle power lamps for the 16-candle power therefore. The lamps on the 6-light cluster lanterns were also modified towards the end of August by the substitution of 8-candle power lamps for the 16-candle power lamps

ELECTRIC LIGHTING MEMORANDA.

The "unsound investment" held up for examination in last week's *Money* is the Maxim-Weston Electric Light Company. This is one of the electric lighting concerns of the day; started in the first flush of the speculating fever, with a showy Board and plenty of money, and the rights to half-a-dozen patents. There has never been the unanimity of dealing in this Company's shares which startled the City in the case of the Brush concern; yet its shares have reached 12, representing a gross value of £926,487, whereas they are now at 1 nominal—no dealers—or an apparent loss of £880,912. As a matter of fact, however, our contemporary hints that the "sound investments" have not even this small value. One of the objects of gibbeting these unfortunate Companies in this manner is avowedly to throw light upon the actions and motives of Mr. William Abbatt, the advertising stockbroker, in whose category of "sound investments" they have all appeared at various times, and have in this way been recommended to inexperienced investors all over the country. What must have been the result to confiding readers of these plausible advices need not be detailed. The Maxim-Weston is one of the electric lighting companies that still exist, and it has honestly tried to do business; but the Fates are against it.

The second annual meeting of the Faure Electric Accumulator Company has just been held, when the notorious M. Philippart, newly released on bail from his arrest on a charge of fraudulent bankruptcy, attended to give "explanations" to the assembled proprietors. There was, of course, no dividend; but the Chairman was able to describe how he had driven a tramcar in Paris by means of accumulators. Of course, the same thing cannot be done here half so well as in Paris. According to the majority of these speculative electricians, they can always do more wonders a long way off, and when nobody is looking, than before the coldly-critical eye of the world. Mr. Ayrton, on this occasion without his double, was on hand to tell us once more as to the infinite superiority of the Faure-Sellon-Volckmar battery for all purposes except earning a dividend. From statements made to inquiring *shareholders*, it would appear that the old Board of Directors left £120,000 in hand, which is all gone. The Company is hopelessly mixed up with a number of French Companies, in a way not explained in the report. The Chairman left the proprietors with the pleasing assurance that if he should be locked up again he thought their affairs in France would be on badly. It must be all for satisfactory, therefore, to reflect that they could not be much worse than they are now.

At length it is announced that the electric lighting machinery of the Fulmen Company is in working order, and the various courts will therefore be henceforth opened at night. As the *Iowa* is essentially a summer one, it might have been thought that the great cost of providing electric lighting machinery was unnecessary. Whatever may be the effect of the lighting—and, under the circumstances, it should be very good—the expense will be enormous. There is apparently no machinery on the ground to light all Kensington; yet the work has been delayed in consequence of a repetition of the usual fault of electricians in underestimating the power required for their dynamos. Thus it is reported that Messrs. Davey Paxman and Co., of Colchester, who supply the motor engines, have had to increase the available horse power by about one-half beyond the figure first stated, and that in any case their engines will be much over-driven to keep up with the work. It is therefore fortunate the exhibition is so successful that there will be no difficulty in finding money for this extra luxury of lighting.

The two latest and most remarkable additions to the list of electric lighting installations are Buckingham Palace and the Royal Courts of Justice. Messrs. R. E. Crompton and Co. have fitted up the latter establishment for the Swan Company; and it is to be hoped that the work has not been done in a manner "too scientific" for the Lord Chief Justice, who on at least one occasion had to call for some candles in his court. The lighting of the Palace is said to be very good; but as it is only to be used when State balls are given, it will not be visited many times a year. In both cases it may be supposed that expense has not been much considered; but the economising statement is promulgated that for the Law Courts lighting the "cost of maintenance and repairs will not exceed 25s. per hour, the cost of the gas lighting being said to exceed £2." This is an awful "way of putting it, for it will be observed that only the cost of "maintenance" of the electric light is given. Still, it will be something fresh to learn that electric lighting can compete with gas in a Government building, not usually regarded as the home of economy, while quite a different result is obtained everywhere else.

FAILURE OF THE ELECTRIC LIGHT AT THE "CITY TEMPLE."

A correspondent writes us that on the last night of the year 1882, just before the arrival of Dr. Parker's evening (about 8½) sermon, the forthcoming lecture of the Edison Company employed for lighting the "City Temple" suddenly went out, and it is needless to remember that nearly in less than no time crowded the fact that the 20 lamps played some "fantastic tricks" in the construction of the heavenly canopy, and were assembled in the "Temple," listening to the Rev. Arthur Dakeyne Dr. Stenciphone. The immediate cause of the failure of the lights then was a breakage of a wire at the end of the lecturer's library, and the current supplying the lamps being thus broken, the light went out, and attended by a startling, crackling, hissing noise, accompanied by a flash of blue flame. On the present occasion however, the effect was totally different, and the cause will have to be sought elsewhere.

The correspondent says: "It cannot be stated positively how the current broke—whether the wires became disconnected or the engine, broke down. The fact remains that the lights were all extinguished at the precise moment of the collapse of the electric lighting arrangements. There was one partial, but very feeble lamps at intervals going out in several parts of the building in the course of the evening; but fast Sunday evening the light was not so brilliant as on Christmas Eve, and nothing noteworthy occurred until the fatal moment, when, without the slightest warning to the building, suddenly assumed a peculiar reddish colour, very feebly portrayed to the assembly, made a sudden 'leap' in the direction of the ceiling, and expired with the waning year. At the time of the electric light mania Dr. Parker's then Manager contrived to catch the electric fever, and the building has been handed over to the Edison Company for their experiments in; but the stanchest advocates of the light have been disappointed in the present instance. Dr. Parker paused for a moment for a general feeling of distrust among the congregation; but the speaker was equal to the occasion, and the service was proceeded with. I am glad to record that the instantaneous turning up of the gas by the verger saved the building from a panic and confusion, and such timely service should certainly not be allowed to pass unrequited."

ELECTRIC LIGHTING MEMORANDA.

A letter signed by Mr. Henry G. Calcraft, on behalf of the Board of Trade, and relating to electrical supply licences, was published in the London newspapers on Saturday last. This official missive was addressed mainly to Electric Lighting Companies, who may be supposed to be mailing their representations at this time for next year's campaign. Observing the difficulties and delays of the Provisional Order system, some Companies appear to have thought of applying for licences, to begin with; perhaps with the intention of improving their position as time goes on. Mr. Calcraft points out, however, that licences cannot be granted for a longer period than seven years; which does not allow sufficient time for the full and commercial development of any system of electric lighting in large areas. The Board of Trade have therefore determined not to grant licences to undertakers (other than local authorities) for wide areas, such as the whole of a provincial town or a London parish. If speculators want to try their fortune in a large district, they must make up their minds to accept all the responsibilities of obtaining and carrying into effect a Provisional Order. They will not be allowed to play with the locality for a short time, to the exclusion of others who might be inclined to establish a more permanent business. This is a wise decision; but it will probably be loudly complained of by electricians, as another block upon their progress; especially by those who only want another excuse for subsiding into the embraces of an official liquidator.

Of all the frightful examples of the consequences of precipitancy in adopting electric lighting, there is none to surpass Hull. When the idea was first made popular in England by the unceasing efforts of interested persons, the local authorities of Hull rushed to the conclusion that they must have an Electric Lighting Act all to themselves. Consequently, before it could be put in operation it was found necessary to go to Parliament for a general Borough Act, in which the powers obtained a year before at such a cost could have been included for a mere trifle. As it was, they were mercifully before being utilized. After this second Act was passed the Corporation did not know what to do with the electric lighting part of it; and when, after many shines, the whole thing would have been allowed to drop. It was felt, however, that some steps should be taken to satisfy the natural expectations of the ratepayers; and consequently a contract was made with Messrs. Siemens Bros. and Co., Limited, to light a portion of the town—a very small portion, because it was not desired to spend much money upon the lighting, the permission for it having already cost so dear. The conduct of this experiment in the beginning was not satisfactory to the townspeople; and, after much negotiation with the eminent firm who were doing the work, the terms of the contract have been rearranged, and the time of the engagement is to be reckoned from the date when the lighting "is shown to be in accordance with the contract." This phrase does not mean the perfection of lighting; for it recently transpired, at a meeting of the Town Council, that several members hold the opinion that the lighting has never been satisfactory at any time, and never will be, although we may agree with the terms of the contract. One discontented councillor actually expressed a desire to know whether the Siemens system was really the best! These expressions of dissatisfaction received considerable strength from the fact that the street gas-lamps had been lighted every night, as usual, since the electricians began their work. At Messrs. Siemens's request, however, the gas is to be left unlighted henceforth, as an experiment. So that the present condition of affairs in Hull is not so much an experiment in electric lighting, as a trial whether the electricians can do without the gas-lamps.

The financial results of experimental street lighting by electrical supply companies is shown in the case of the Maxim-Weston Company and the Clerkenwell Vestry. Twelve months ago the Company entered into a contract for lighting Pentonville Hill, and began with incandescent lamps. Although largely advertised at the time as a success, this system soon had to be changed for arc lamps. The contract is now on the point of completion; and as the Company are drawing their responsibilities, they will not renew it at any price. However, they still cling to the plant to the Vestry for £9000, or half the stated original cost. Hence it may be judged how profitable the work has been to the Company. It is not at all likely, moreover, that the Vestry will agree to pay even that reduced price for plant which they can scarcely know how to manage. It should not matter very much to the Company whether they sell their plant for old metal or as a going concern, for the game is very nearly played out.

The electric lighting—or rather darkening—of Eastbourne is making the inhabitants and visitors of this pleasant town clamour for the restitution of the discarded gas-lamps. In this case the Local Authorities appear to have had more faith than the Town Council of Hull, for they freely removed the old lamps before convincing themselves that the new ones would work well. Unless we are mistaken, the Eastbourne experiment is under the experienced hands of some of the Brush people, although the peculiar territorial name of the undertaking has escaped us. It is a curious fact that while seaports and watering-places have been very liberal in trying electric lighting for their "parades" and principal thoroughfares, an air does not agree very well with many of the systems experimented with; for there have been more failures in such localities than anywhere else. There may be reasons for this, or it may be only a coincidence. It is at least a tolerably well-established fact.

Journal of Gas Lighting &c.
Aug. 21st, 1883.

THE ELECTRIC LIGHT COMPANY MANIA OF 1882.

Our contemporary *Money*, in a summary of the past financial year, says: "The year 1882 will be a memorable one for electric lighting companies and their expenses. We have, if for nothing else, at the electric lighting exhibition, a most remarkable instance of what "lights" really means. In this year only early in April that the total recalled the zenith of its ambition. Since then it has been gradually shrinking, and at the moment of writing, not more than 1000 lamps—at lighting strictly estimated. The completeness of the crush may be read easily enough in the following figures. On May 30, Brush 21 shares were quoted at. On May 1 they had fallen to 10½ and to-day (Dec. 23) are ranked 6½. Hammonds, £2 10s. paid, are to-day 1s. 6d. Swan rose up to £1; fell to 5 in November; and to-day are at 3½. The Anglo-American and other companies are at a discount, and generally unmarketable; and the whole of the speculative interest in the matter of the light itself, also deaths of the existing companies such as Edison. The companies have been started on a principle against which we have consistently protested. We have shown the billionaires of all rated companies. These applied a large capital they can show an out-of-all but a patent, which may be superseded or disputed; and that the process has the one disastrous object of enriching patentee and promoter at the cost of the shareholders."

ELECTRIC LIGHTING MEMORANDA.

THERE is a rich crop of electric lighting news this week, and it is almost a pity that the necessarily limited space which we are able to devote the these matters will only permit of the most cursory mention of the more striking items. To begin with, the report and accounts of the Anglo-American Brush Corporation—the English parent of all the Brush Companies—have been published. Our caustic contemporary *Money* thus ravaged these interesting documents in a spirit which may be understood from the simple mention of the fact that the startling phrase, "Founded on Rain," is the heading of its commentary. It appears that the Corporation has suffered a sudden check in its ordinary business of manufacturing and selling machinery; the value of its unsold stock and plant being about £80,000. From this or other causes it seems that the Directors have found it needful to make a call amounting to £80,997. It is pointed out by our contemporary that while at the close of the year there had been received the sum of £21,222 on account of this call, the cash at the banker's was at the same time only £20,588; hence the conclusion is drawn that but for this timely call the concern would have been in debt for cash to the extent of £2631. On the contrast for lighting the portion of the City thoroughfares allotted to them the Brush Corporation was debited with a loss of £1696, exclusive of establishment charges. These latter are enormous; the salaries and miscellaneous expenses being £21,520, while the Directors' fees amount to £25,997. For this outlay on management and staff there is shown a nominal net trading profit of £12,500, which is partly dependent on the realization of the stock. The disastrous Lane-Fox patents, or some of them, are to be resold to this ingenious personage; and it may be imagined that the Directors sincerely wish they had never touched them, for thereby an opening has been made for litigation of which no man can see the end. The general balance-sheet contains an entry of £192,950, being the assumed value, as an asset, of shares held by the Corporation in part payment for concessions. This asset *Money* cheerfully appraises at something less than "a threepenny-bit" in cash. Altogether, therefore, although it is acknowledged that the concern is not on its last legs yet, for there is a balance of calls unpaid, and others may be made, the Corporation are decidedly under a cloud. The *Directors* "pride themselves on the "extraordinary prosperity" of the early part of the year; but our contemporary sternly refuses them for taking credit for a brief good fortune that was seen the beginning of their end; and *Money* evidently thinks the parent organization will speedily follow them.

Not long ago the readers of *The Times* were informed, by the American correspondent of that journal, that Mr. Edison had addressed himself with perfect success to the problem of competing, with his incandescent system of lighting, against gas at ordinary English prices. We promptly discredited this statement, and felt at the time that it would not have been difficult to expose the real condition of the *Edison* experiment upon the Holborn Viaduct. All evidence upon this point is, however, met at once with the objection that this installation is purely experimental, and therefore does not prove that establishments similarly constituted on a scale will share its defects. At the same time its successes, such as they are, are not similarly limited; but the assumption is made, with great confidence, that all defects will disappear and all perfections be multiplied in large establishments. We are not likely to see one of the latter class of undertakings in England for some considerable time; but from New York, where something of the kind has been attempted, there comes a statement to the effect that Mr. Edison has not quite succeeded in competing with gas even at 8s. per thousand cubic feet. At a certain "down-town" printing establishment, seven Edison lamps were set up in place of five gas-burners. Owing, however, to persistent defects of the carbons, it has been necessary to light one and sometimes two gas-burners in addition to the electric lamps. Even under these circumstances the Edison Company's statement of account for light supplied from Oct. 10 to Nov. 10 shows that the total amount of light furnished was equal to 18,240 standard candles, for which, at the Company's price of 1 dol. per thousand candles, the charge would be 18·25 dols. This represents the work of one lamp during 1020 hours; whereas the charge for gas at the same time in other parts of the building was after the rate of 10·95 dols. for 1095 hours, or about 85 per cent. in favour of gas. To addition to this must be reckoned the cost of the gas-burner or burners used in aid of the incandescent lamps, which, though defective, are of course charged for as perfect. Under such circumstances the above "printing" office would be paying the Edison Company for the equivalent of gaslight at 18*s.* per thousand cubic feet.

Interest has been created by a letter from Mr. Coope in *The Times*, describing the process through which he was led to adopt incandescent electric lighting for his mansion near Colchester. It appears that he first obtained an estimate for a private gas-works, which would have cost altogether £1200. The electric lighting installation has cost £1470, showing a slight excess over the estimate for gas. The result of the experiment, so far as lighting is concerned, is described as satisfactory. Up to this point Mr. Coope stands upon the firm ground of facts; but he proceeds to give an account of the annual working expenses, to which the fatal word *estimate* is prefixed. We all know what estimates of electric lighting are, and how unaccountably they fall short of the reality. It would, therefore, have been better if Mr. Coope had waited until he had enjoyed his experiment for at least a year, and had then given us the actual cost, with any observations that riper experience might have suggested. As to the latter aspect of the question, another *Times* correspondent addresses an awkward question to Mr. Coope, as to whether he can, by the new system, have any light at all except at fixed times, and if the whole or a large portion of the machinery must not be set to work for a single light. Mr. Coope's reply to these searching inquiries, which, indeed, go to the heart of the matter, is more apologetic than reassuring. And he is badly supported by Mr. Sellon, who seizes the opportunity for advertising the secondary batteries in which he is known to be interested. In fact, Mr. Sellon damages Mr. Coope more than the openly sceptical correspondent already mentioned. Mr. Coope thinks he will get his 200 lamps alight for £150 hours for an annual charge of £292 15*s.* 1*d.* We hope he will write again a year hence, and say (with equal regard to the pence) how near this estimate is to the truth.

Some time ago Mr. Lane-Fox delivered a lecture, at the Royal United Service Institution, on "The Future of Electric Lighting," which has since been published. The lecturer has a vivid imagination, to which he gave full scope on this occasion, emitting prophecies which even *Engineering* shrinks from endorsing. Among his liberal promises was one to the effect that "we [*i.e.*, the electricians] could retail energy at "one farthing per hour per horse power; that is, we could actually produce the power and sell it at a profit at that price." And as he also said that 1-horse power would give light equal to 160 candles, it is superfluous to add that he demolished gas lighting there and then, and without hope of recovery. Unfortunately, Mr. Lane-Fox was only able to employ in one kind. He did not foresee what has actually come to pass, while the rest has not—that all the Brush Companies who took up his own valuable patents would soon get rid of them in the greatest hurry, and at any or no price. Last week an extraordinary general meeting of the Yorkshire Brush Company was held for the purpose of considering an offer for the repurchase of the Lane-Fox licence for £95,000 *in the Company's own shares*. The entire arrangement is a sorry farce, for the supposed purchaser is the Electrical Works Company, now in voluntary liquidation. The Directors conticence in question embodying a cash payment. The Diamond Company are, of course, mixed up in the transaction in some mysterious way. After desperately trying to get a little cash for the licence from the representative of the nominal purchaser, the unfortunate Yorkshire Brush proprietors were fain to "tip out" their property for the consideration already stated. These are some of the phases of that "future of electricity" which Mr. Lane-Fox did not anticipate.

Guyscer's Journal Sept. 1882

Electric Lighting for Domestic Purposes.—Progress in the arts in our age is often so rapid and so completely upsets old established industries and institutions that the public has grown accustomed to be very sanguine in its expectations of what new things will do. The telephone is an instance in which the most salient hopes of its inventors have been realized. The electric light has required and will require much more time for its successful introduction. When, three or four years ago, promising inventions in the conversion of power to light through the medium of electricity followed one another in rapid succession, public excitement ran high, and there were many who predicted that at an early date our gas manufacturers would be ruined by powerful competition. The happenings of the past few years have shown how far these sanguine predictions have come from being realized. The gas interest is as powerful and as prosperous as ever, and there are no signs that it will be soon crowded into a secondary position. The electric light has conquered a field which gas had never been able to fill satisfactorily, but it has not practically perceptibly invaded the territory of its older rival. For large spaces and for show, and possibly where power is cheap but suitable coal expensive, we now have the brilliant arc light, which renders many of our public places, streets, shops, and places of entertainment brilliant. In such cases, intensity of illumination and places of enterprise at greater cost. For domestic lighting, the brilliant and powerful arc is quite unsuitable, and even for the illumination of our ordinary rooms, the difficulty of attaining greater diffusion by increase of number and decrease of power of individual lights has not yet been overcome. Nor have we any positive proof that the electric lighting of streets is cheaper than gas, even at present prices of the latter. Since 1878, Mr. Edison has been experimenting with his incandescent light, which it will be cheerfully conceded has many special advantages when compared with gas. It is healthier, cleaner, cheaper, neater, and safer. The great and decisive question whether it is cheap enough is now to be tested on a magnificent scale, though it must be noted that there are special circumstances favorable to it in this case. Recently, a beginning was made to illuminate a section of the lower portion of this city, and it is expected that soon about to the thousand Edison electric lights will be in operation. It is, of course, too early to speak with any show of confidence on the point how far economies are of some dissatisfaction about the power of the lights, but this may be partially a disappointment after undue and unreasonable expectations. On the question of cost, we have no data that may be accepted as conclusive. By laboratory experiment, by a theoretical comparison of candle-power of gas against candle-power of incandescent electric light, we know that the latter is still beyond in the race. But it remains to be seen whether consumers are willing to pay for other advantages more than that difference in cost, as based on present prices of gas. As to the latter, though the gas companies have always maintained the closest secrecy as to their operations, we know that they could afford to reduce their figures very materially, and yet leave a very good margin for profit. Though the challenging public attention much less than its younger rivals, gas-lighting has during the past few years been much improved, both as to methods of manufacture and devices for burning, and a more liberal spirit has partially offered the measure of past high-handed action.

After a careful survey of the field, we can but believe that the light which has now begun in earnest will not help believing that the On the one hand, we have electrics and strong advantages in the way of better light; on the other, the powerful ally of lower cost. We would caution our readers therefore to look with caution on announcements of the undoubted and unqualified success of the electric light. They should bear in mind, too, that Mr. Edison hopes to derive much of his small profits in fact, it is stated that he looks for such a profit on this branch that he can afford to do the lighting at a reasonable loss. It is hardly necessary to say that such exceptionally good opportunities would not be offered anywhere else as in the business portion of this city.

ELECTRIC LIGHT

A DEPARTMENT OF THE

AVALANCHE

Devoted to the intelligent discussion of Improvements in Electrical appliances the publication of the News of the time in its sphere, and particularly to

ELECTRIC LIGHT

ROSS EDGAR RAYMOND, Editor, 46, TAVISTOCK STREET, COVENT GARDEN, LONDON.

Introductory.

Electric Light having become an accomplished fact, and its commercial existence being fully demonstrated, it assumes the relation to the world of finance of any other great business project.

The Electric Light and Power Companies that have been formed in Great Britain within six months have capitalized at the enormous figure of £25,000,000. Their shares are distributed with every class of investors, and their plans, as yet, for the most part existing only in the merit of the inventions upon which they are based, present unsettled points that may well have the careful consideration of promoters and investors. It will be the duty of the Electric Light Department of this Journal, to form the link between the two classes most interested, and to present the merits of all systems with the accuracy and reliability that belongs to the result of a careful unprejudiced investigation.

Unfortunately among the systems upon which are based some of the plans of many of the companies now clamouring for public attention are a number utterly unworthy of confidence. In some cases their patents are not properly made, in others they are unblushingly stolen from worthy inventors, and the shares themselves are being floated upon the representations of the prospectuses that have no foundation beyond the fertile imaginations of those who wrote them. In the mad rush of investors for Electric Light Securities, these companies have been able to bait their hooks so temptingly—and always at the expense of the solid institutions—as to secure as the reward of their effrontery large returns.

It will be the duty of this department to wage an aggressive warfare upon such pirates, and by the exposure of their plans to leave open to the reliable ones that field of profit which is legitimately their own.

A number of so-called electricians have recently succeeded in victimising capitalists, and have been the means of organising companies that cannot last.

It will be the duty of the Electric Light Department of this Journal to expose such men.

Just at this time the World of Science is directing more of its attention to the investigation of electricity than to any other subject: out of all this investigation will come nearly every day new and important discoveries.

It will be the duty of this Department to faithfully record these as they are made from time to time.

To the end that the objects held in view by this Journal may be attained, correspondence and expressions of opinion are invited. All communications will either be published or returned. Names and Addresses must accompany all material.

It is our intention to publish papers on Electric Light and Power subjects, from men of highest authority and eminence. So that end we have already secured articles from Mr. Edward H. Johnson, the Manager of Edison's interests in Great Britain, who will write on the future of Electric Power; the present holder of the Faure Electric Storage Batteries Patentee; H. S. Maxim, Herr Siemens, Lieut. Sprague of the U.S. Navy, a rising young electrician of America, who served as a juror in the late Electric Light Exhibition at the Crystal, Palace, and others. Further articles from equally eminent sources will follow. Each number of the paper will contain the quotations and range of Electric Light, and Power Shares, and a review of the market. In short, it is our intention to make this Department of this Journal a necessity to the class whose interests it will faithfully try to represent.

There will be a strong fight in Parliament over the Electric Light Bill. The Companies will resist the limitation of 15 years, and make a strong effort to get the time extended to 21 years instead. In doing this, they are only endeavouring to obtain less than was allowed to the gas companies in their infancy.. All the testimony elicited by the committee that framed the bill indicated how necessary it is that electric light companies should have ample time to get their undertaking well [illegible], and twenty years was named as the very shortest [illegible]od.

Revised Copy.

ELECTRIC LIGHTING.

A LECTURE

DELIVERED BY

J. W. SWAN,

BEFORE THE MEMBERS OF THE LITERARY AND PHILOSOPHICAL SOCIETY OF NEWCASTLE,

THE PRESIDENT (SIR W. G. ARMSTRONG) IN THE CHAIR,

OCTOBER 20th, 1880.

NEWCASTLE-UPON-TYNE:
MAWSON, SWAN, & MORGAN, 24, 26, & 32, GREY STREET.
1880.

THE "ELECTRIC LIGHT" AT ALTRINCHAM.

One of the most successful lectures of the series given in connection with the Bowdon (Literary and Scientific Club that has been delivered in the Literary Institute, Altrincham, on Tuesday evening by Professor S. P. Thompson, the subject of the lecture being "Domestic Electric Light." The apparatus, by means of which Professor Thompson performed his numerous interesting experiments, was kindly lent by Mr Charles Lever, of Oakbrook Hall. The large room in the Institute in which the lecture was delivered was lighted by three of that gentleman's improved arc lamps, and a number of others were placed over the doors in the building. Favourable notices of these lamps have already appeared from time to time in the columns of some of our London contemporaries. At the exhibition now being held at the Crystal Palace, Sydenham, they have attracted a large share of attention. The electric current by which the lamps were supplied on Tuesday evening, and during the experiments conducted, was produced by a Siemens and a Hefner-Alteneck dynamo placed in the yard adjoining, belonging to Mr Joseph Heginbottom. They were worked by a powerful steam engine on the premises, and were excellently well, under somewhat disadvantageous circumstances, and were the subject of general remark and admiration from those who attended the lecture, of whom there was a large number. The chair was occupied by Mr W. H. Tatton, Esq., and the chairman, in introducing Professor Thompson, said that gentleman's name was one of such world-wide reputation, and they as Altrincham had already so much interested in a previous lecture of his, that it would be unnecessary to do more than ask him to proceed with the lecture.

Professor Thompson, who upon rising was heartily received, then said that he once again invited his readers to come to Bowdon to say something to them, he was quite aware that the subject of a course from which an electric light might be expected, was not such as to go down well. Mr Charles Lever, as many of them knew, had been at work during the year long and laborious forms of an electric lamp. About that lamp he should have more to say presently. The subject of electric lighting was such a lively one to many people, and presented so many points that were not yet generally understood, that it might be well to start right from the beginning, even at the risk of telling what to some of his audience was old and stale stuff; and say how the electric light was first found out, how generated and distributed, and how and why they made use of certain properties of electricity for the purpose of obtaining a light. These large lamps were called arc lamps, and the smaller ones were more or less incandescent lamps. As there was a great difference between these two kinds, it would be well to explain at the outset what it was. The means used that night to get exciting the electric current, were to be found in a yard behind that building, where there was a steam engine and two of those wonderful generators known as dynamo-electric machines, commonly termed dynamos. These machines were of a totally different order to those little toys they were accustomed to in the south, and which consisted of a wheel of glass turned by the hand against a silk rubber. They were so powerful that he should not be surprised if some of his experiments failed, not because there was not enough, but because there was too much electricity; in fact, he should not wonder if it were to burn his apparatus. He would now endeavour briefly to give the history of the discovery of electricity as far back as 1800, was due to an Italian named Volta, who, in the year 1800, invented the Voltaic pile. This consisted of a number of zinc and copper plates, piled up and separated by pieces of flannel moistened with acidulated water. When the wires from both ends of this pile were connected a small spark was obtained. On the 20th of November, 1800, this Italian wrote a letter, addressed to a scientific assistant, living in the town from which he (Professor Thompson) came—Bristol—and one of these piles, after trying to get a spark he found that he could get a shock by touching the tip of the wire between his tongue and the other. That person was Sir Humphrey Davy. A year or two afterwards it was found that the pile was the means by which a current of electricity by this means, two metallic wires, say one of copper, for instance, were immersed in a cell containing acid and water, and this produced a current as soon as the two wires were not provided round the outside. In this case, however, the zinc was being consumed by the acid, and therefore impossible to obtain an electric current without the consuming of the zinc. There were various kinds of cells, some of which might, however, was sufficient to produce a current for lighting purposes, but which was [illegible] battery." Such a battery of 12 cells it was a comparatively easy matter to produce a powerful electric light. Of course, if more cells were taken a more powerful light was produced. Professor Thompson next showed how the light was generated. If, he said, he took two pieces of carbon in his hand, and passed a current through them, he could, by first joining and then separating them, get a spark between them. The separation must be rendered instantly hot, and they slowly burnt away. The points being gradually consumed, the space between them increased, and the wide that it offered too great an obstruction for the passage of the current, and the flame would go out. In order to obviate this, about 40 years ago a regulator was devised which could hold the carbons near enough to each other in their proper distance, moving them together and separating them when required. The carbons had to be made to touch; it was not sufficient to bring them near each other, because the current would not leap across the thousandth part of an inch. Then they must be separated by about the thirty-seventh part of an inch before it would leap across for the spark. When that was done they burnt, as they consumed, he gradually moved towards each other, so that there was never more and never less than the thirty-seventh part of an inch between them. That was the difficult problem to make a lamp which should fulfil these conditions. It was done, however, by a person named Duboscq, by means of a clock-work arrangement controlled by an electromagnet. This clock-work arrangement was not entirely successful, in consequence of its complication. It was apt to get out of order and go wrong in many ways; and it required continual attention and regulating. Being too fine an instrument for commercial purposes, it had simply remained a philosophical instrument, a modification of it being used in some lighthouses. Recently, however, Professor Thompson said that if the means he had already described had been all that had been discovered for lighting, lighting would not be in the position it was to-day, because the means of generating a current by a galvanic battery was too insufficient and far too dear for commercial purposes. The first improvement, therefore, was to get a cheaper and more economical source for producing an electric current. That cheaper and more economical source was not the consumption of any other kind of fuel in the battery. Coal was found to possess a greater power of heat than was required for producing a current, but coal could not work in a battery. It was of no use to make it into gas, because, in fact, it would not act at all in that sense. So the modern way of generating an electric current was to get it entirely different from the galvanic battery as a steam engine was from a good dinner. (Laughter.) When a year ago he had the honour of lecturing before them on the subject of magnetism, he showed how, by winding a coil of wire round a rod of wire, the very fact of moving it into the coil, or taking it out, generated a feeble current of electricity. This principle, which was the foundation of the first dynamo-electric machines, was discovered by Faraday. In these machines coils were made to rotate in a magnetic field. Steel magnets were found not to be strong enough; therefore electro-magnets for more powerful. Electro-magnets were therefore used. These consisted of coils of wire wound round soft iron, and through which a current of electricity was then sent. The lecturer next mentioned the different varieties of machine, and explained their several peculiarities. Among these were the Gramme, the Siemens, the Alliance, the Brush, the Edison, and the Burgin. In the year 1878 a new kind of lamp was invented by Mr Jablochoff, with all its machines required for regulating it. This, and this was known as the Jablochoff candle. This candle was not a very simple device, for, instead of having a clock-work mechanism to bring the carbons together, two pieces of carbon were placed side by side, exactly at the right distance from each other, and so could never be anything else. They were separated by a thin film of plaster of Paris, and as they consumed away the light gradually passed from one end to the candle. In fact, they were just like a candle with two wicks. But a current of electricity when it passed through carbon was a very long carried little bits of charcoal with it, and so both carbons did not burn equally. One burnt twice as fast as the other, and how to get over this difficulty was one of Jablochoff's further suggestions. That was a very satisfactory lamp in many ways, but it was [illegible] for lighting purposes, and could not be used [illegible]

lamp made on that principle was Gerard's. Amongst the more famous of those lamps was the Brush. There was no clock-work arrangement in the Brush lamp. Professor Thompson said that among other lamps, that who had invented a simple arrangement for regulating the cartons, by means of what was known as the "hair spring," was Sir Lloyd Sir Lever, whose lamps were being used only for them that night. (Applause.) He had also to say that he had not a photograph of the clock-work arrangement of Mr Lever's lamps, and therefore he could not describe it; and do the best he could in making a sketch of them. The various parts of Mr Lever's lamp were then sketched on glass by the lecturer, and projected on to a screen. It was impossible, said he, to imagine anything simpler, and therefore he considered that lamp the best, or, at the least, certainly one of the best ever invented, as being simple and efficient that he could not but think it had a great future before it. (Applause.) After referring at some length to the lamps Professor Thompson said that he had to deal with one kind of lamp only, he had yet to mention the smaller ones. Those he had been describing, beautiful as they were, were far too bright for ordinary use, but very large drawing-rooms, or likewise, though that were not fitted for such a hall as that, and for streets, they were most convenient and economical, as they got an enormous amount of light for their money. The smaller lamps, he said, had been adapted for household purposes, but he might not say that at present they were cheaper than gas on the other hand, perhaps they were dearer. After a lengthy description of the various kinds of incandescent lamps, including the Edison and Swan lamps, Professor Thompson said that the next question was, how were they supplied with light? The question was not, however, a very difficult, but could correctly of electricity by means of wires, and the manner in which the electric light was supplied was cheaper than gas when a great deal was required—that there was as yet no cost established where a comparison could fairly be drawn. For in no case except two, and those could not be taken into consideration, was there any instance of electricity being supplied at a price less than gas was charged. At Godalming, for instance, they were going to make a fair comparison, but they must wait a little longer. He (Professor Thompson) was a dynamo machine in his yard and the man who had in erect his own gasometer and meter and make his own gas. If a comparison were made in that way electricity was the day on the score of cheapness. As things were at present, they would be no more the galaxies than the men who had to get a set the meter and pay so much per so much per 1000 gardens. From every other point of view the electric light was far in advance of gas. Its brilliancy, the atmosphere was not polluted with it, and colours could be seen better than by gas. In conclusion, Professor Thompson said he would only add that he knew the electric light in general use before long, feeling sure it was only a very small part of a very great subject. We wanted electricity distributing for other reasons, leading motive power, and a hundred other purposes, for which electric engines might be used. He believed that the electric light would be followed as shortly for its use largely supplied by electricity, in fact, it would prove a most valuable ally, not only for the rich man who wished the luxury of a bright light, but to a poor man also.

On the motion of Mr Alfred Neild, seconded by the Rev. J. E. Odgers, a vote of thanks was accorded to the lecturer and Mr Lever, and the proceedings then terminated.

Menlo Park Scrapbook, Cat. 1018

No. 11H. "Electric Light"

This is the eighth of nine scrapbooks containing clippings about electric lighting. It covers the years 1881-1884. The book contains approximately 130 unnumbered pages.

Electric Light-

11. St.

ELECTRIC LIGHTING MEMORANDA.

Some of the facts concerning the electric lighting at the Savoy Theatre are beginning to leak, notwithstanding the great secrecy that is maintained respecting the expenses. The amount of capital that has been sunk in the installation is still undefined, but it is well known to have been very large. It is to be regretted, from an engineering point of view, that the details of cost of the generating and distributing plant have not been made public, in order that an estimate might have been formed of the relation which these two divisions of capital expenditure bear to each other. It is believed that the distributing arrangements have been reorganized more than once, which would entail heavy additional expense beyond that represented by the miles of insulated wire actually in position. The machinery has also been running for sufficient time to at least indicate the allowance that should be made for breakdowns and wear and tear, respecting which we are yet kept in ignorance. With regard to the working expenses, however, it has been stated that the cash payments amount to about £27 weekly, merely to keep the establishment going, without reference to interest on capital, repairs, or depreciation. Besides this the gas-rental is reported to average £10 weekly; or a total for lighting of but little under £40 every week. The expense of lighting the building entirely with gas amounted to about £22, so that the comparison in this case is not very favourable to the electricians, who, be it remembered, do not pretend to receive a return for their outlay, but in the above account merely to charge the weekly cash out of pocket. It is impossible to escape the reflection that the Electric Lighting Companies, who called Dr. Siemens as a witness before the Select Committee on the Electric Lighting Bill of the Board of Trade, had ample justification for refraining for putting in evidence the facts of this unfortunate experiment. It is idle to pretend, as was there urged on behalf of the Companies, that the cost of electric lighting can only be ascertained from the working of great undertakings, having a capital expenditure of from £100,000 to £200,000 per square mile of town population. Why could not this Savoy experience have been cited in detail, with every item separated, and a statement made on the facts, showing the points (if any) in which a supply from a central station would be cheaper? This is the kind of evidence which the Committee had a right to expect from Dr. Siemens and the other eminent authorities who were called, one after another, to guess at the capital cost of electrical installations. Precise knowledge is to be gained sometimes by arguing from the known to the unfinally decline to follow, to their own discredit and to the perpetuation of confusion.

The tide of opinion respecting the relative prospects of gas and electric lighting is still setting strongly in the way indicated in these columns last week. Newspapers which have until lately indulged without stint in prophecies referring to the imminent pre-eminence of the new luminant, now find it expedient to pay some attention to the facts of the present. The *Pall Mall Gazette* of Thursday last, for example, contained a very temperate article in which the records of a number of experiments were adduced in support of the assertion that not one penny has yet been saved to ratepayers by any Electric Lighting Company, whereas most of them have added considerably to the expenditure for light. This was with reference to are lighting in public thoroughfares, although instances of railway stations and other large buildings were also mentioned. The sole exception admitted was the notorious South Kensington Museum example, where the lighting of the Lord President's Court is reported to have cost £250 per annum with electricity, as against £660 with gas. These figures have been paraded with such pride by electricians, in prospectuses and elsewhere, that it is worth while to insist here that what has been gained in expense has been lost in effect, and that the system of gas lighting adopted at South Kensington—the simple and effective design of running lines of burners round the rooms at the top of the walls—is, perhaps, the most costly arrangement known. At any rate, this apparent triumph of electricity has not been repeated elsewhere, and it is only employed to a very limited extent in the Museum. With reference to incandescent lighting, the *Pall Mall Gazette* admits that the facts are few; but it is said that the Edison system is reported, under certain conditions, to be cheaper than New York gas at 8s. per thousand cubic feet. Our contemporary confesses that it is doubtful whether similar results will be obtainable in this country. As to this we are enabled to state something from Mr. E. H. Johnson's evidence before the Select Committee on the Electric Lighting Bill. Edison lamps will be supplied on the Holborn Viaduct, for the benefit of those guileless persons on the Stock Exchange and elsewhere who never look beneath the surface of a transaction, at the same price as gas. Surely this will be regarded as securing the downfall of gas lighting in this country, even before a similar effect has been produced in America!

Journal of Gas Lighting &c
May 9th 1882

ELECTRIC LIGHTING MEMORANDA.

An estimate of the cost of an electric lighting establishment on the Brush system has been supplied by the Hammond Company to the town authorities of Peterborough. This establishment is calculated on the basis of 80 lamps, which are only supposed to be required for 1000 hours during the year, or rather more than 4½ hours nightly. The plant—comprising two No. 8 dynamos, 80 lamps, with four spare ones, wire, lamp-posts, and 40-horse power semi-portable engine—would cost £1691, on an estimate which is at any rate, not parsimonly full. Having started the undertaking on this basis, the working expenses are made up as follows:—Labour, £310; coals, at 3 lbs. per horse power per hour, £220; depreciation, at the rate 2 per cent. on dynamos, 5 per cent. on lamps, and 10 per cent. on engines, amounts to £258; and "sundries," at £30, neatly brings up the total to £1000 per annum. Carbons for the lamps form an admitted extra of £100, and it is noticeable that all charges for interest on capital, oil and water for engine, and other items which will, of course, at once occur to every user of steam machinery, are totally omitted from this statement. Every entry in the estimate of working expenses is distinctly illusory, not to use a stronger term. It is not our purpose, however, to correct this imaginary estimate as it stands; but it may be remarked, if the Brush system is making such wonderful progress in the hands of the Hammond Company, why do they not publish the duly attested accounts of some existing establishment—say Chesterfield—as a guide for future customers, instead of continually drawing upon the fertile imaginations of their staff?

Messrs. Compton and Gordon have written to *The Times* on the subject of the fire risks of electric lighting, and have appended to their communication the code of rules drawn up by the Engineer to the Phœnix Fire Office for installations of electric lighting in buildings which are technically regarded as "hazardous risks." These electricians appear to have had in view the pacification of the public mind on the subject, which might be disturbed at the rumour that the Insurance Companies have decided to charge extra premiums for buildings electrically lighted. They maintain that the now system of lighting is absolutely safe if properly managed; but that

It is naturally dangerous if left in ignorant and careless hands. It is not to be ignored, however, that at the Paris Electrical Exhibition at least six alarms of fire arose from the conduct of exhibitors who might have been expected to know how to manage their own affairs. The greatest danger in electrical fittings carrying intense charges of electricity is, moreover, the absolute want of warning of anything amiss until the damage has been done. A leak from a water-pipe is sufficiently obvious; and the same may be said of an escape of gas. Yet it is well known that the appearance of the right way of dealing with an escape of gas still prevails, notwithstanding the simple character of the precautions necessary to be observed. May it be hoped that the far more subtle dangers of electricity will be met in a more satisfactory fashion than has been experienced in the case of danger from gas?

A few observations which recently appeared in the City Article of the *Daily News* sufficiently indicate the character of the prevailing rage for electrical speculations. It is said that the trade in the shares of these concerns, which are brought out by the dozen every week, is so brisk as to attract many dealers from other and less active departments of the Stock Exchange. This simply means that the game is kept up smartly, as a matter of speculation. From the context it appears that the writer of the notice in question had in view mainly the subscriptions to the Brush Company and its numerous concessionary offshoots. He goes on to say that nearly everybody is of opinion that Brush shares will rule higher, yet that it is astonishing how little is known as to the profits on lighting by the Brush processes. The only explanation of this prevailing ignorance is that possibly those most intimately acquainted with the subject do not care to publish their information. The writer of the paragraph proceeds to observe that the market is getting into a state which would predispose it to a scare, were any rival enterprise to prove successful. The possibility of a scare, which would bring the shares of all similar speculations down to one hopeless level, is always to be reckoned upon under the conditions described. Here are subscription lists opened and filled up to the extent of hundreds of thousands of pounds, when it is acknowledged that little or nothing is known respecting the profits of the business in which the money is sunk. When the revelation comes, it may not be particularly welcome.

Journal of Gas Lighting &c
June 1881

THE ELECTRIC LIGHT IN THE HOUSE OF COMMONS.—At the close of the morning sitting of the House of Commons, on Friday, the experiment of lighting the House with the electric light was tried. Twelve square lamps for the electric light, and twelve for gas, were placed, one and soon after seven o'clock, when the House was closed, the experiment was made in fate operation. The effect was, *The Times* says, doubtful; there was no difference of opinion among the members and others as to which was, on the whole, the skilfully applied gaslight from the glass roof was not softer and less trying to the eyes than the electric light. It was conceded, however, that to one respect the electric light was an improvement on the gas, inasmuch as the rising temperature always noticed in the House after the lighting of the gas was not perceptible in the case of the electric light. The electric light was severely tested by the strong sunlight which streamed in before six o'clock, but it was thoroughly under control, and the House transacted the business of the evening, sitting under the new light. It is intended to make another trial on Friday next. Alterations will be made in the lights in the roof, and additional lamps will be placed under the galleries, where there are now gas-jets. The experiments were carried out in the presence of Mr. Shaw-Lefevre, First Commissioner of Works, and a large number of members and visitors.

ELECTRIC LIGHTING MEMORANDA.

The Leeds Corporation have had a report on the subject of electric lighting from a joint deputation from three of the Committees of the Town Council, which had been appointed to examine the matter with a view to the lighting of the new municipal buildings. The conclusion of the deputation, after they had visited the exhibition at the Crystal Palace, interviewed the managers of several electrical supply companies, and diligently made extracts from various contemporary journals (especially the latter)—is to the effect that the Leeds Corporation should wait and see what further improvements will be made in electrical apparatus; and not adopt any existing system. This is commendatory caution and sufficiency; and the Council should be grateful for such a sensible report from members of their body, who may be credited with impartiality, notwithstanding the interest which the Corporation of Leeds hold in gas property. The deputation collected a great deal of useful information as to the prices of electrical apparatus and lighting estimates; but it might have been wished that more discrimination had been observed in the selection of authorities on certain points. For example, the charge for the Brush lighting in the City of London is put forward as an imitation of the cost of working the system, when it is notorious that the Brush Company have repeatedly declined to take other contracts on the same terms. The ridiculous estimate of cost which recently appeared in the *Engineer*, and which was criticized in our pages at the time, is also drawn upon for data. On the whole, however, the deputation seem to have possessed a remarkable power of coming to a wise conclusion upon questionable statistics.

The game of floating Electric Lighting Companies goes merrily on—new ventures appearing every day, while the shares of the older speculative Joint Stock Companies still hold their own. It will be remembered that a short time since concessionary "Dale Coffee" Companies for every division of the civilized world were formed from a parent association, which had not at the time made a pound of "coffee," or paid a shilling of dividend on its own account. Similarly, all points of the compass are drawn upon at the present time for titles for Electric Lighting Companies, formed to take up concessions from a single organization, which has declared one dividend supposed to be earned by selling machinery at an exorbitant price. Meanwhile new systems are being exploited at the cost of hundreds of thousands of pounds; the latest—we write under correction, for the prospectuses flow in so fast—being the Gülcher Company,* with a capital of £800,000, not less than £75,000 of which is to be devoted to paying the happy inventor whose name is borne by the enterprise. The Stock Exchange just now is indeed a "happy hunting-ground" for electricians. High-sounding names can be had for directorates for the mere asking; and the money flows in, or appears to do so. Meanwhile gas shares continue to mount in value, and so everybody is pleased.

Earnest attention is now being directed to the valuation of the fire risks of electric lighting, and there was a large gathering of fire insurance authorities at the rooms of the Society of Arts on Wednesday last, when Mr. Jas. Dolas discoursed on the subject. Much of his address was wide of the point at issue, although interesting as an exposition of some of the rarer phenomena of ignition and combustion. The lecturer introduced a code of rules for electric lighting installations, which had been prepared for the Phœnix Fire Office by Mr. Heaphy. These regulations are calculated mainly with a view to ensuring ample size and separation of the combuting wires, and the avoidance of danger from the sparks of carbon which drop from arc lights. Mr. Dolas suggested that complete by-pass arrangements should also be provided, together with other precautionary measures which need not be described in detail. He also stated that, when suitable precautions are taken, the dangers incident to electric lighting are no greater than those incident to gas lighting; and that one point in favour of electricity is that it is only liable to effect ignition, and not feed the flames like a melted gas-pipe. On the other hand, the lecturer did not mention the danger to life which

* The correctness of three, if not four additional Companies have been advertised since this paragraph was in type.

might be incurred by firemen in the act of hurriedly cutting off a circuit wire with an axe, if it were observed to be setting fire to woodwork. The lecturer, of course, performed the smashing it, in order to prove the harmlessness of the incandescent lamp. This is a pretty toy-experiment, but sufficient lamps have already been sacrificed in its performance, since nobody dreads fire from this quarter. What is more to the purpose is to fairly state the conditions under which fires are really imminent, and to show that they can be avoided in a satisfactory manner. The last word has not yet been spoken on this subject; and neither has the last fire occurred from this cause.

June 14, 1881.

"As a curious instance of how New York deals of FIRE insurance Underwriters, the subject of unheralded nocturnal light mines came up for discussion. One or two accidents have occurred from an electric light wire coming in contact with a telephone wire. It was suggested that the electric light companies to insulate their wires. Any building in which the mode of lighting is used will be rated as specially hazardous unless the insulation of the wires be perfect.

Dr. Paget [the author of "The Electric Light in its Practical Application," and for years a member of the Council of the Laboratory of the celebrated Wheatstone, is reported to have made some important improvements in electric lighting. Apparently the novel feature in the invention is that in the use of an infinitesimal arc; that is, the distance between the poles of the lamp is so slight as to be scarcely perceptible. It is said that the lamps, which vary 7 or 8 of Swanne's gas cells, will give a light of 40 candles. The Doctor is also reported to have overcome the difficulties experienced by M. Faure in storing electricity.

ELECTRIC LIGHTING IN THE CITY.

On Thursday night last the long-promised exhibition of electric lighting in the City of London commenced. It may be remembered that as long ago as last August the Corporation determined to institute an experiment in electric lighting for several of the principal thoroughfares of the City, including the three City bridges over the Thames. It was decided that the district devoted to this exhibition should be divided into three parts, which were to be separately contracted for. Messrs. Siemens Bros. taking the line of streets from London Bridge, past the Mansion House, to the Guildhall; the Anglo-American Electric Light Company (the Brush system) following with the remainder of Cheapside, through St. Paul's Churchyard and Ludgate Hill, to Blackfriars Bridge; and, as originally arranged, the Electric and Magnetic Company (the Jablochkoff system) were to have taken up the lighting of Queen Victoria Street, including the cross street to Southwark Bridge. Eventually, however, the last-named contractors dropped out, their place being taken by the Company working the Lontin system—the change causing such delay that the thoroughfares in question were not included in the scene of the display of Thursday night, which, therefore, consisted of the Siemens and the Brush lights in their respective districts. We have already described how the Siemens lights are divided into two classes, the one being composed of large lamps, nominally of 2000-candle power each, suspended on signal-posts eighty feet high; and of the other class consisting of smaller lights ranged in the ordinary way along the footpath upon posts about twenty feet high. The large lights are in clear glass lanterns fitted with umbrella-like reflectors, and the smaller lamps are in frosted globe globes. It must be said at once, after careful inspection of the examples in the City, that the lofty lighthouse system does not recommend itself for street use. The so-called large lights are no more than the well-known regulator-arcs, and possess the old defects of unsteadiness, glaustiness, and of casting dense sharp shadows. It is difficult to see what is gained by hoisting these strong lights up so much out of the way at the comparatively open spaces where they are placed. Much of the light is wasted on the upper parts of the neighbouring buildings, while by the time the light reaches the roadway it is greatly enfeebled, without having any other advantage. If the electric arc-light must be moderated or diluted in some way before it can be used for street lighting, it is evident that this object may be better attained by the use of globes which at the same time help to diffuse the light, than by retaining the well-known disadvantages of the naked arc, modified only by passage of the illuminating rays through space. Messrs. Siemens' small lamps are more successful, but do not attain to perfect steadiness, neither are they altogether satisfactory in point of colour. Still they are greatly superior in both respects to the Jablochkoff candles as exhibited on the Victoria Embankment.

The Brush lamps are of that can be desired in illumination of this kind. There can be no question of their superiority to the Siemens lamps, as there is no doubt of the advantages possessed by the latter in comparison with the Jablochkoff candles. The Brush lamps are fixed alternately on each side of the pavements, on pillars about thirteen feet high, the rather small frosted or opal globes containing the light being covered by an oblong reflector. The light afforded by these lamps, said to be of about 2000-candle power each, is of good colour, well diffused, and very steady, offering a pleasing contrast in these respects to any other arc-light of which we have present knowledge. It would, of course, be premature to pass judgment on the whole exhibition until an opportunity is afforded of seeing the remaining portion lit up by the Lontin lights, when—including the Brockie light at the Cannon Street Station—five different methods of lighting by the carbon are will be visible in London in close proximity to one another; but at the present time it must be acknowledged that the honours fall to the Anglo-American Company for the beauty and steadiness of their light.

All that has been said above must be considered as the preliminary observations which any careful observer of the present exhibition would make before attempting to decide upon the import of the whole thing as illustrating a possible means of lighting the busiest thoroughfares of a great city, in substitution for gas. As our epigrammatic neighbours across the Channel have aptly put it, illumination is one thing, lighting is another. It has been decided in Paris that the electric light, as there shown, is illumination—splendid, dazzling it may be—but not lighting. Upon careful consideration of the necessities of foot and vehicular traffic through the crossed streets of this City, it must be granted by an impartial observer that the present experiment in the line of thoroughfares from Blackfriars to London Bridge affords further proof of the truth of the French saying. The quality of street lighting must be valued by the amount of light received in the darkest part of the road. The fairness of this principle can scarcely be called in question. This being granted, we are fred to maintain that, as far as can be judged without precise measurement, the amount of light available on the footpath in Whitehall, between the new gas-lamps recently erected by Mr. Sugg for The Gaslight and Coke Company, is equal, if it does not slightly exceed, the degree of illumination to be observed in a similar position with reference to either the Siemens or the Brush electric lamps in the City. Small and not particularly clear print of a type one size smaller than is ever used in the JOURNAL, is readable in both cases, and therefore it may be conceded that such lighting is quite good enough for streets where, as in this country, people are not in the habit of sitting or standing to read the newspapers. But if gas and electric lighting are to be judged with equal power under these circumstances, further consideration of the method in which the power is in each case supplied points incontestably to the superiority of gas. It will not be denied that, for all purposes of vision, an area dimly but uniformly lighted is preferable to one dotted over with powerful lights, at such intervals that no part of the field illuminated is absolutely darker than the darkest of the former. So in a thoroughfare lighted in its darkest parts equally well by gas and electricity, the strain on the eyes of a passenger, caused by the latter passing momentarily between a space of light and semi-darkness, is much more distressing than when, as at this time in Whitehall, the same wayfarer may walk from one end of the street to the other without being made painfully aware of the means by which his steps are lighted. From the point of view of omnibus drivers and others, who, while passing along a street at a quick pace, must, in our narrow streets, and from their elevated position, be continually exposed in an especial degree to the worst effects of electric street lighting, it is very easy to believe that the experiment in the City may not be hailed as an altogether unmixed blessing. But considerations of this kind can only be fairly weighed after a duly prolonged experience of the advantages and disadvantages of the new system. The experiment is now fairly launched, and must be allowed to go on to the appointed end. If we were so fond of prophesying as some of our electrician friends, we might be more fully disposed than we really are to indulge in anticipations of the end. We are more inclined to wait for results than to predict them, either on the promptings of our hopes or fears. In any event, the termination of an experience in methods of street lighting, as we hope and believe, will not be an occasion for either undue exaltation or despondency on the part of those who, while looking on street lighting as an important branch of business, yet draw the greater portion of their revenue from other sources.

Journal of Gas Lighting &c
April 5, 1881.

NOTES FROM SCOTLAND.

(FROM OUR EDINBURGH CORRESPONDENT.)

EDINBURGH, Saturday.

At last there has been a stirring of the pool in Edinburgh with respect to public lighting, and it only needs one agitating electric light company would rush in, as one could foretell what would happen, in order to get a company as well as to the public. It may appear strange that the announcement that two members of the Corporation have had the temerity to move a motion, which will be discussed at its next meeting of the Council, that a remit be made to the Cleaning and Lighting Committee to consider, and report upon, the question of applying the electric light to the thoroughfares of the city, with a view to make such preliminary inquiries as they may deem necessary; but to the uninitiated it will be plain that it is not at all unlikely that the motion will be carried. It is not let it be supposed for a moment, however, that the interest centres in the Council, or in anything relating to electric lighting. Such a view would be erroneous. That the remit been to report upon the expediency of adopting parafin, it would have received an (quasi) welcome; because in many of the less frequented streets and closes of the city that fluid is really constitute the bulk of the public lighting, as I have had occasion to remark on a former occasion, and as the newest applogies for gas. The Gas Corporation is not to blame for this, for I see, by the last published statement of the shareholders, that the gas supplied, that that of the Edinburgh Company was equal to 32 candles, and supplying gas, I understand the Companies have nothing to do with the lamps. If the Corporation of Edinburgh, either bodily or individually, have any objection to the introduction of electric lighting companies, I could easily understand why the lamps of the city should have been allowed to continue in such a disgraceful condition as they have been, but under what direction it comes, will be heartily endorsed by a large section of the community; and if the Committee's opinion be taken in favour of experiments with the electric light, I have no doubt that a report will be favorable to the long benighted city. The contrast will be the greater that gas, in everything relating to the matter of expense, will fall into comparative insignificance. While the Corporation Committee will be considering the question, the Gas Company will have the superintendence of the lamps, but they will be carefully overhauled; that all unworkable governors—and they are legion—will be removed; and that a good or fair amount be spent in cleaning the glass of the most improved burners. With these alterations, a light of 32 candles can really be obtained from the hourly consumption of 14 cubic feet of gas, which is the allowance for each lamp, would be obtained, and there would be no necessity for new leases for the introduction of any other method of public illumination. An experiment at the east end of Princes Street—at the Register and Post Office—has proved that better lamps, has been such a success as to warrant the extension of the system. Were these, or other lamps of similar construction, substituted for those in the western end of Princes Street, an effect would at once be produced which would be a credit on the city, and show off to some advantage the natural beauties of a street of which every native of Edinburgh is proud. In this way, too, the community would have an opportunity of comparing the relative merits and expense of the two systems of lighting.

THE CITY OF LONDON WITHOUT THE ELECTRIC LIGHT.

This late severe weather caused a considerable amount of trouble to gas manufacturers and their customers; but either the climate or something else has had a much worse effect upon the proposed illumination of the thoroughfares and bridges of the City of London by various systems of electric lighting, of which we heard so much last year. This scheme hangs fire in a remarkable manner. At first it was to have been inaugurated last autumn; then it was announced that the 1st of February would see a gorgeous vision of tall lighthouses strung along the side walks, and superseding the gas-lamps. Now it is said that the 1st of March was intended for the commencement of the new system, but that the late snowstorm and frost have so obstructed the preliminary work, that it is yet uncertain when the electric lamps are to make their appearance. Meanwhile, the streets and bridges continue to be lighted by the doomed gas-lamps; for, with an amount of discretion for which they are not always credited, the City authorities have not given the Gas Company positive orders to turn off the gas from the street lanterns on a fixed date, although, of course, unless they wish to go on paying for gas and electricity as well, the day will come when the services of the Gas Company will be dispensed with—for the time being. The Corporation do not appear desirous to hasten the electric lighting contractors, who, we may hope, will give the public a good show after keeping them without it for so long. Perhaps, however, these anxious persons are calmly waiting for summer previous to lighting up, in order to get settled to their work before next winter. There have not been any symptoms of popular discontent with the existing state of things, or of a yearning after a better arrangement; but the Commissioners of Sewers should bestir themselves and get their experiment well forward before Mr. St. George Lane Fox, or some other electrician with equal experience in street lighting, brings forward a new system in order to upset Messrs. Siemens, Brush, and Jablochkoff together.

ENGINEERING NEWS
AND
AMERICAN CONTRACT JOURNAL.
VOL. XIII. SEPTEMBER 16, 1882. No. 37.

THE EDISON SYSTEM OF ELECTRIC LIGHTING.

A certain quantity of electricity passing through a good conductor produces no physical effect on the conductor; but a constriction in the conductor or an interposition of a material that is not so good a conductor causes an effect analogous to that of a large quantity of water violently forced through a small pipe—an crowding of the particles, causing friction and consequent heat. Upon this simple principle all electric lights operate. In both the arc and incandescent lamps there is a resistance present at the point of illumination, and heating occurs.

It is our purpose in what follows to briefly describe the recently inaugurated Edison system of electric lighting as now in operation in this city.

The Edison Electric Light Company was organized in October, 1878, with a capital of $300,000; this has been increased on two occasions until it is now $720,000. The company owns the patents of Thomas A. Edison, and under them its operations are carried on. Although the lamps and dynamos of Mr. Edison have been extensively used both in this and foreign countries, nothing was tried in the way of general illumination from a central station until the dynamos were started in this city on the 4th inst. This district embraces the area bounded by Wall, Nassau and Spruce streets and the East River; the dynamos are located at Nos. 255 and 257 Pearl street. During the early part of the present week we visited the general offices of the company at 67 Fifth avenue, the central station, and also many of the users of the new light.

THE STATION.

The boiler room is located in the basement of the building. There are now in place four Babcock & Wilcox boilers and four others are being prepared, which will give an aggregate horse-power of 2,000, working under a pressure of 120 pounds. The four boilers are arranged in pairs facing each other and at a sufficient distance apart to permit the fireman to attend the furnaces. The coal is received in bins placed under the sidewalk, and is then shoveled into a trough in which works a screw, and which leads over the first set to the space between the boilers. The ashes are thrown into a receptacle under the flooring and conveyed out by the same plan. A Sturtevant blower furnishes the blast needed by the boilers, fresh air for ventilation and for the dynamos, as will be mentioned later. Two smoke stacks, one for each set of boilers, extend up through the centre of the building to the roof.

The first and second floors of the building were removed and an iron superstructure erected entirely independent of the walls of the building, and resting on separate foundations. On this the dynamos are placed. We could not obtain a satisfactory explanation to our query as to why the heavy machinery in rapid motion was elevated and the dead load placed on a solid foundation in the basement.

THE DYNAMOS.

There are six dynamos now in position (this number will be doubled as soon as the equipment is completed), the armature of each being driven by a Porter-Allen engine having a cylinder diameter of 11 ¼ in. and a stroke of 10 in. These are directly connected and are expected to make 300 revolutions per minute.

The armature is of the Siemens pattern: its foundation, or core, which is built upon the shaft, consists of a series of sheet iron discs, separated from each other by layers of thin paper and bolted firmly together. This method of constructing the armature, while it has all the advantages of solid iron, prevents the great loss of power which is produced or local currents, which would be present if it was one piece. The face of the armature is made up of heavy copper bars, having a trapezoidal cross-section, their dimensions being ⅝ by ⅞ of an inch. To insure a perfect insulation, each bar is wrapped in Japanned paper and separated from the iron core beneath it and from its neighbors, by an air space.

There are the same number of copper discs as there are bars, one half being at each end of the core. Each disc has two projecting lugs, one on each side, these lugs being placed nearly but not quite diametrically opposite to each other. The discs are bolted together so as to form, with the iron discs constituting the core, one solid mass. Each end of every bar is connected to one of the lugs.

Air from the blast enters horizontally opposite the center of the armature, and, as the space above mentioned permits of a free circulation through the parts, all liability of the accumulation of heat is prevented and the capacity of the machine greatly increased. In order to resist the centrifugal force developed by the high rate of speed, the bars on the armature are wound with piano wire at certain places.

The commutator in these dynamos consists of 40 bars of copper placed longitudinally on the shaft and separated from each other by an insulating material and connected with the armature bars. So, each bar on the commutator forms the terminus of a continuous loop or convolution through the copper ribbons on the armature.

The brushes are composed of certain layers of fine copper wire and plates soldered together.

The armature is 27.8 inches in diameter and 21 inches in length; the armature shaft is of steel, 2½ inches in diameter and 10 feet 8 inches long; the commutator is 12¾ inches in diameter and 18 inches long; the journals are 6¼ inches in diameter, 10 inches long, and have bibbitted steel rings in pillow blocks of the box pattern. In order to prevent undue heating by friction, constant lubrication is provided for and there is a continuous current of water flowing beneath the boxes.

The magnet is composed of two large pole pieces of cast iron, having semi-cylindrical faces, between which the armature revolves. These poles are 49 inches wide and 61½ inches high. To these poles are attached twelve cylindrical cores of soft iron, wound with coarse copper insulated wire, through which the electric current passes. Four of these cores are attached to the lower pole piece and eight to the upper. The twelve cores are 37 inches long, the eight upper ones having a diameter of 8 inches and the four lower ones 9 inches. There are four soft iron keepers, 11 by 9 inches securely bolted together and attached to the cores.

The current from one of the mains of the commutator passes through the wire wound upon the nearest middle core, thence to the one directly above; then to the one beneath; from here it takes the same course through the other three vertical cores in succession. Before entering the other main the current circulates through a resistance which increases or diminishes the magnetic attraction as may be needed by the demands.

A safety catch is placed on each dynamo. This consists of a break in the conducting wire which is filled with a piece of metal having a low fusion point. Should any undue heating occur, this metal is fused, and a break thereby caused in the circuit, and the main and lamps saved from any possible injury.

Each of the six dynamos weighs as follows:

	Lbs.
Armature and shaft	1,500
Two pillow blocks	1,440
Magnet, complete	33,000
Pole pieces	980
Total	44,810

The copper used in construction is distributed as follows:

	Lbs.
Armature bars	1,200
Armature discs	1,200
Magnet wire	1,500
Total	3,400

The magnet rests upon insulating bases of cast zinc 3 in. thick. The dynamo and engine are mounted on a base plate of cast iron, made in two parts for convenience, and bolted together.

This bed plate is 14 ft. long, 8 ft. and 9 in. wide, and weighs 10,300 pounds. The entire weight of the steam dynamo is as follows:

	Lbs.
Dynamo	44,810
Engine	24,450
Base plate	10,300
Total	80,570

After leaving the dynamo the current passes through a circuit-breaker, which consists of two sets of copper plates, the upper set being so arranged that it can be raised from the lower or depressed, so that the plates will overlap and insure a perfect contact.

The electric current from all the dynamos is led into a common main, from which branch the various feeders leading into the street and supplying the district.

A test line leads from the dynamos to a room upstairs, upon one wall of which are grouped one thousand lamps, so arranged that any number of them can be placed in the circuit. The current from any one of the dynamos can be sent through the test line to the lamps and its power thereby ascertained, and its real working condition or capacity obtained.

Each of the dynamos has the nominal power of a 1,200-light machine at 16 candle-power incandescence. This can be readily increased to 1,400 lights of the same power without heating the armature or in any way heating or burning the brushes or commutator. This result is accomplished most economically, and is due to improvements in the lamp itself.

The mains, which may be said to collect the current from the several dynamos, lead along one wall of the room to the front where the connections are made with the feeders. At this point a piece of low fusion metal is inserted in each of the lines of the feeders in the same manner and for the same purpose as already described.

In the room above is an indicator for keeping the electro-motive force within certain defined limits. The current passes through an electro magnet, before the face of which is an arm held back and away by a spring. The power of the magnet depends upon the electro-motive force passing through the coil. A too powerful or too weak current is shown by the lighting of a red or a blue incandescent lamp. Watching these lamps, the attendant, constantly at hand, throws in or removes resistance coils as the case may require.

THE DISTRIBUTING SYSTEM.

The word "distributing" may be aptly applied to the method of placing the electric current at the disposal of the patrons. An iron pipe is laid underground through the streets, and protects two heavy semi-cylindrical bars of copper, which are perfectly insulated both from each other and from contact with any outside object. At the station each of these bars is connected with the mains from the machines as already described. These bars enter an iron box at every place where it is desired to "tap" the current, and wires are attached leading into the house. Low fusion metal is here again inserted. The box is then filled with an insulating compound and the caps securely bolted in place.

METERS.

Each consumer is furnished with a meter consisting of a bottle containing sulphate of zinc, in which is immersed two bars of zinc, kept at a constant distance apart. An infinitesimal portion of the current passes through the meter, causing a decomposition which increases one of the zinc bars and decreases the other. At stated times these bars are taken to the station, and the difference ascertained. As a certain quantity of electricity will produce an invariable effect—in this case decomposition—the quantity which passed through the meter can be readily computed, and as this bears a known ratio to the current entering the premises, that can also be found. One most decided advantage in this arrangement is that the consumer pays only for what he uses. "An inferior 'quality' of the illuminant will never affect the reading of his meter."

THE LAMPS.

The lamp consists of an exhausted bulb of glass, pear shaped, and containing a loop of carbon made from bamboo, and of a thickness a little larger than a horse hair. The ends of the loop terminate in two platinum wires passing through the ceiling, and so situated that when the lamp is placed in its socket these wires will form contact with those leading from the street and carrying the current. By turning a key the current can be shunted from the lamp. An accident to one lamp has no effect upon any other in the same circuit. Each lamp is provided with a portion of the low point fusion metal so often alluded to.

FIRE PRECAUTIONS.

It is one of the laws governing the action of dynamic electricity that an absolutely complete circuit must be established before we can obtain at any current and upon the occurrence of this circuit in any point all effect instantly ceases. As stated in the beginning of this article, heat will be developed where there is any undue resistance. Owing to these reasons Mr. Edison has adopted the most effectual means for breaking the circuit and destroying the current before any dangerous amount of heat could be developed. A metal with a low fusion point, or one which will open the circuit at a low temperature, has been placed between the several points of the conductors at every point where the guardian powers were deemed desirable. In case of the destruction of this metal at any place it can be easily and quickly renewed after

ence cause has been ascertained. No danger is possible from the lamps themselves, as the fracture of the globe destroys the light instantly.

Interior illumination by incandescent lamps may be considered one of the institutions of this city, and judging from the favor with which it has been received, its growth is only a question of time—a short time at that. The economy, safety and brilliancy of the light commend it for almost any purpose, and its absolute freedom from noxious vapors will endear it to all lovers of pure air.

[NOVEMBER 11, 1882

THE ENGINEERING AND MINING JOURNAL

The Electric Light in Cotton Mills.—A series of very interesting figures on the cost of electric lighting in cotton mills in New England, as collected by Mr. G. J. H. Woodbury, the agent of the Manufacturers' Mutual Fire Insurance Company. It is difficult to make a comparison between the various methods of illumination, because a change of light in always made an excuse for more light. Most mills are lighted with gas made by the destructive distillation of petroleum and of about 80 candle-power, which is generally reduced to 60 candle-power by using air mixed with it. The annual cost of 40-gas per burner is from 75 cents to $1; in all these estimates, interest at six per cent forms one item, and in the large corporation, with exceptional privileges, makes the coal-gas at an annual cost of 69 cents per burner. Another corporation, however, makes gas at a cost of $1.19 per burner. Of two large mills in the same manufacturing similar goods, the more modern one consumes gas at an annual cost of 70 cents per burner, while the older one consumes coal-gas at $2.05 per burner. The longer time the light is required, the lower the cost, the average cost, because, with the addition of operating expenses, the interest on plant, being a fixed amount, becomes a smaller proportion of the whole cost. A dark mill, that is, one of which the interior walls are not whitened, requires about twice the number of lights that are sufficient in a white mill, and the light, almost one hundred hours a year more, 600 hours per year is the average. The cost of arc lights in several steam mills running 3,000 hours per year is 6½ cents per hour, of which 1¼ cents are for carbons, 2½ cents for attendance, coal, depreciation, and interest. In a weaving room, on very fine work, arc lights have been used, the arc-foot gas burners, which consume 2.62 c.h. This foot per hour; therefore, are light represents the consumption of 17272 c.h. feet of gas per hour. A careful estimate shows these arc lights to be costing 6¼ cents an hour; therefore this new lighting system represents gas at 39 cents per 1000. A similar installation in another mill gives the annual cost of gas $2188, and electric light at $1135, or 52 cents per 1000. The annual saving in fuel will in lighting expenses by the use of electricity makes a profit of from 10 to 20 per cent on $17,716, without making mention of any improvement in work or production due to that light. In the case of incandescent lights, the cost is more difficult to estimate, because they are run at all degrees of brilliancy, affecting both the power and the life of the lamp. Both the Edison and Maxim lamps are guaranteed to average 600 hours; yet in the New York Post-Office, the average record is 1,200 hours; 14 lamps started to be 1800 hours on September 1st, and 13 lamps had already burned 3400 hours. The ferry-boat Jersey City, belonging to the Pennsylvania Railroad, is lighted by the Edison lights, and their record has been given to me as averaging 1645 hours, and the lamps are burning. In the Merrick Thread Company's mill at Holyoke, the monthly cost of lighting by gas furnished by the city was $228. By substituting Edison incandescent lights, the cost was brought down to $53.62 per month. The Holyoke Water-Power Company furnishes water-power very cheaply; and as a result of the use of the Edison lights was to bring the cost of lighting a mill to the equivalent of gas at 67 cents per 1000 feet. Charles W. Lippitt, of Woonsocket, R. I., said that the Globe Mills had been supplied with the electric lighting system, which was much preferred to gas. For the seasons of 1881 and 1882, the company had used 177 large lights, running them for 807 hours, at an actual cost of $237.83. Those took the place of 220 gas burners, which, burning four feet of gas per hour for 807 hours, cost $710.40. The saving in favor of electric lights was $425.77, or an actual saving of 57 per cent. In another mill, oil-gas is used, and although it can be supplied at a lower cost, its results are not so good as coal gas. The cost of running 220 burners of oil-gas for 307 hours is $478.11, which still leaves a margin of $145.38, or 31 per cent in favor of the electric lights. Col. Thomas Livermore, of the Amoskeag Mills, said that they had 5000 lamps lighted with 465 electric lights, which had during the last eight months consumed 91,000 carbons. The average cost of each lamp per hour is 2·80 cents. He had found that one arc lamp could take the place of twelve gas burners, supplying 12 lamps with light. His mills manufactured colored goods, and a stronger light was found necessary to distinguish the colors. They had supplied fifteen sewing and spooling rooms with the lights.

N.Y. Scientific Times & Mercantile Review

THE KEITH ELECTRIC COMPANY.

Now Introducing the Keith System of Electric Lighting—The Advantages Thereof.

There has been more rapid progress made with the electric light within the last three years than with probably any other invention that was ever brought out in any part of the world. What scientific men, here and in Europe, not long ago declared to be impossibilities are now accomplished facts, and electricity looms up as the great and wonder-working force of the age.

Among the newer candidates to public favor in this direction is the

KEITH ELECTRIC COMPANY,

who have just opened an office at 201 Broadway and 52 Nassau street, this city. They are manufacturers of electric machines, lamps and other apparatus for electric lighting and power. The company are operating under the patents taken out at different times by Prof. D. E. Keith, one of the ablest of the many scientists who have given their attention to the study of the capabilities of electricity. A reporter for the Scientific Times called at the above address yesterday and interviewed Prof. Keith, who exhibited the light invented by him in practical operation. It is whiter, stronger and steadier than any other electric light yet seen in New York, and the company will undoubtedly prove to be a powerful competitor to those already in operation. They are ready to give estimates for lighting streets, public and private buildings, steamships, wharves, etc. Prof. Keith has invented a system for the storage of electricity, a full description of which the Times hopes to be able to give in a later issue.

It will be in order to refer here briefly to the electrolytic process for refining and separating the gold-containing base bullion—a process that is rightly looked upon as one of the great discoveries of the age. Even the "Wizard of Menlo Park," Thomas A. Edison, declares that it will be a commercial success, and there is no doubt entirely such matters that he.

Base bullion is a product of the mines of Nevada, Colorado, California, Utah, Arizona, New Mexico, and various other States and Territories. The yearly production of base bullion now exceeds 100,000 tons, and is rapidly increasing with the discovery and development of new mines. It is the product of nearly every silver reduction by smelting furnaces, and otherwise, the rock and other worthless matter having been removed, leaving only the metals, to wit: Gold, silver, lead, copper, antimony, and other metallic substances as originally in the rock. About 90 per cent., upon the average, of the base bullion is lead.

The problem is to extract the lead from the base bullion, with the lowest possible expense. Before the bullion can become bullion, it has to pass through a refining process for the elimination of the antimony, copper, and other metals, which are more or less injurious to the quality of the bullion. The refining process is a very simple one, and is carried on in reverberatory furnaces, which are heated by the combustion of coal. The bullion is placed in the furnace, and the heat is applied until the bullion is melted. The antimony, copper, and other metals, which are more or less injurious to the quality of the bullion, are then skimmed off, leaving the bullion in a pure state. The bullion is then cast into bars, and is ready for the market.

LIGHTING A GREAT CITY BY ELECTRICITY.

Doctor Siemens, in his usual practical and lucid style, has given some figures on the cost of lighting the planet proposed for the lighting of such a city as London by building main stations and establishing electric mains in the shape of copper rods of good thickness, with branches wire-drawings in all directions. Doctor Siemens is averse to such a plan, and by way of illustration, takes the parish of St. James's, London, which has a population of 29,865, contains 3018 inhabited houses, and has an area of 781,000 square yards. Assuming that the task of domestic lighting resembles to the gas companies, and that the electric light is introduced into private houses only at the rate of 12 incandescent lights per house, the parish of St. James's would have to be provided with electric energy sufficient to work 36,180 lights, or 362 horse-power effective. The cost of building a large underground chamber, to contain the machinery, the cost of boilers, engines, and dynamo-machines necessary would be £140,000. The quantity of copper for conductors in the entire system would be nearly 185 tons, and would cost £15,125. The iron pipes would require £37,500 additional, which would carry the total to £177,000 for providing for one quarter of the consumption in lighting the parish of St. James's alone. Dr. Siemens goes on to say: The large aggregate of dwellings comprising the metropolis of London covers about 70 square miles, 30 of which may be taken to consist of parks, squares, and sparsely inhabited areas, which are not to be considered for our present purpose. The remaining 40 square miles could be divided into, say, 110 districts, slightly exceeding a quarter of a square mile on the average, but containing each fully 3000 houses and a population similar to that of St. James's. Assuming 20 of these districts to rank with the parish of St. James's (after deducting the 600 shops which I did not include in my estimate as central districts), 50 to be residential districts, and 40 to be comparatively poor neighborhoods, and estimating the illuminating power required for these three classes in the proportion of 1 to 1½ to 2, we shall find that the total capital expenditure for supplying the metropolis with electric energy in the ratio of 28 per cent of the total lighting requirements would be say £14,000,000, without including underground and internal fittings. To extend the same system over the rest of Great Britain and Ireland would absorb a capital exceeding certainly £100,000,000, while a total capital expenditure of £250,000,000 would be required to work the United Kingdom. Some of us may live to see these figures realized, but the end would be attained, I feel sure, only in more tentative and by the more interesting appliances to produce work representing this value of machinery and power, and economized by the breath of many years of practical experience.

The amount of the working charges of an establishment comprising the parish of St. James's would depend on the number of working hours in the day and on the prices of fuel per ton. Assuming the 81,000 lights to increase for the hours a day, the price of coal to be 20s. a ton, and the consumption 2 pounds per effective horse-power per hour, the annual charges under this head, taking eight hours' being enough assumed to about £19,800, to which would have to be added for wages, repairs, and sundries, about £9000; for interest with depreciation at 7½ per cent, £13,500; and for general management say £3000; making a total annual charge of £11,000, or at the rate of 12s. 2½d. per incandescent lamp per annum. To this has to be added the cost of renewal of lamps, which may be taken at 5s. per lamp of 16 candles, lasting 1200 hours, or 4s. 6d. per annum, making a total of 20s. 2½d. per lamp for a year. In comparing the results with the cost of gas-lighting, we shall find that if taken 5 cubic feet of gas, in a good argand burner, to produce the same luminous effect as that obtained from a 16-candle incandescent lamp, consuming a burner every day, for six hours on the average, we obtain an annual gas consumption of 10,950 cubic feet, the value of which, taken at the rate of 2s. 8d. per thousand, represents an annual charge of 29s., showing that electric light by incandescence, burning 1200 hours, or 6 hours per annum, making a total of 20s. 2½d. per lamp for a year. In comparing the results with the cost of gas-lighting, we shall find that if taken 5 cubic feet of gas, in a good argand burner, to produce the same luminous effect as that obtained from a 16-candle incandescent lamp, consuming a burner every day, for six hours on the average, we obtain an annual gas consumption of 10,950 cubic feet, the value of which, taken at the rate of 2s. 8d. per thousand, represents an annual charge of 29s., showing that electric light by incandescence, burning 1200 hours, or 6 hours per annum, makes

"ELECTRIC LIGHT."

THE JOURNAL OF ELECTRIC LIGHTING,

AND RECORD OF INVENTIONS, IMPROVEMENTS, AND CURRENT EVENTS IN CONNECTION WITH THIS BRANCH OF SCIENTIFIC INDUSTRY.

No. 1. Vol. I. MAY, 1882. [Price 6D.

INTRODUCTORY.

The general adoption of electricity as a lighting agent, not only for public but for private purposes is daily drawing nearer. The streets; various institutions; places of amusement; the establishments of the wealthy; many of these are already lighted by this agent—or, to speak more correctly, by the new methods of developing and utilising its powers. The list of users of Electric Lighting, too, is daily increasing, thanks to the sustained efforts of scientific men and practical mechanicians, and to the inventions and improvements which have been introduced by this means. In a very few years it may be said that we are within a reasonable distance" of the time when Electric Lighting for all purposes, and under all conditions, will be the rule, and the use of all other artificial lights the exception.

In these circumstances it has been felt that the time has arrived when a journal, dealing with the subject of Electric Lighting, may be usefully and profitably established. It will be the object of this journal to supply users of Electric Light—both *in use* and *in posse*—with the latest intelligence in that special branch of scientific industry, and, as far as possible, to give some account of each improvement in Electric Lighting as it may be introduced; to chronicle the progress which the light is making, both in public and in private; and generally to afford a means of obtaining the latest and most varied information on the subject. In addition to this, papers having for their subject-matter the lives and labours of electricians of eminence will be published. Descriptions of the various existing systems will also be given, and all passing events having any connection with Electric Lighting will be duly recorded; correspondence will be invited, and, in short, every effort will be made to make "Electric Light", truly The Journal of Electric Lighting, and a useful and agreeable organ for the large and rapidly increasing number of persons who are directly or indirectly, interested in the subject.

We desire to have one or two points clearly understood. This Journal will not be, in any sense, the advocate of any particular system. Each, with its most recent developments and improvements, will be described and criticised from time to time without fear or favour. We desire, also, to assure our readers that descriptive notices of any system, or of any machinery or appliances connected therewith will not be—to use plain terms—given in exchange for advertisements. Finally, although in dealing with scientific matters, the use of technical terms is hardly avoidable, it will be our object to avoid them as far as possible; to turn, wherever practicable, the language of science into the language which shall be "understanded of the people."

With this brief explanation of its object and character, we commit our venture to the kindly consideration of the public, in the hope that it may deserve and obtain their support and goodwill.

TO ADVERTISERS.

Whether this journal stone can, of course, only time can tell. To advertisers are, however, invited to note two points. Each month we shall publish the certificate of a public accountant, who will testify to the number of copies which have actually been circulated—not merely to the number of copies which have been printed. And—as we have hinted above—it is not our intention to give laudatory notices of the productions of those who advertise with us, and to ignore or to decry the productions of those who do not. We hope, of course, to have advertisements, and plenty of them; but we hope to obtain them without the aid of wild and exaggerated statements as to our circulation, and without the aid of "notices." In a word, while we desire that our journal may prove a legitimate and successful undertaking—surely a legitimate ambition—we aim at effecting this object by making it a means of conveying valuable or interesting information, and not a mere trap for catching advertisements.

THE GOVERNMENT BILL.

The provisions of the Government Electric Lighting Bill are before the public, and it must be admitted that in their general principles they are good. In detail it is possible that modifications may be necessary, but the strong committee to which the Bill has been referred, together with the criticism which will be received in both Houses before it becomes law, will doubtless suffice for this. It should never be forgotten that the real owners of the electric light are the public, and consequently that the interest of the public should be paramount consumers or users of the light, should be paramount consideration. To say that nothing over every other consideration. To say that nothing in the shape of a monopoly should be allowed to be created, is of course, only to say the same thing in different words, for monopolies, and the public interest are, and will ever remain, in direct opposition. It is satisfactory to note that the framers of the Government Bill seem to have recognised this, and to have not the least intention of repeating the folly of granting perpetual monopolies to any person or persons. Details upon the Companies in these columns that they would be wise in their own interest to take steps

THE "OPERATOR" AND "ELECTRICAL WORLD."

The Edison Installation at Haverly's Theatre, Chicago.

For some months past the Western Edison Electric Light Company has been engaged in installing the Edison light in Haverly's Theatre, Chicago, on an extensive scale, and on April 9 the first exhibition was given under the direction of the engineer of the company, Mr. F. D. Johnston. Gen. Anson Stager, president of the company, being among those present. There are in the theatre 637 lights in all, operated by three dynamos—one for the vestibule and entrances, one for the stage, and one for the auditorium. There is not a gas light in the house now, every jet having been replaced by the Edison globes. There are forty movable bunch lights for use on the stage and forty footlight lights. Then there are five sets of border lights above the stage, two of which contain thirty-five lights each, and the other three twenty-five lights each. The chandelier in the centre of the auditorium, which was manufactured at a cost of $500, bears seventy-four burners, and there are 160 others distributed through the auditorium. In the vestibules and entrances there are fifty-three lights, and the dressing-rooms and stage are also lighted.

Below the sidewalk in front is the new engine, built expressly for the plant, with 200 revolutions per minute. Connected with it are lamps which denote the candle-power used throughout the house. In the first right stage entrance are twelve switches and six resistances for the regulation of the lights. By means of these the lights in any part of the house can be lowered, raised, or entirely extinguished. In the dressing-rooms the lights are independent and can be turned on and cut the same as gas. Each burner is warranted for 600 hours, and will last three or four months in a theatre under ordinary use. Of course the light does away with all danger from fire.

The light given is a soft and mellow one, resembling daylight. One of the actors, who has sung in the Savoy Theatre, London, where the electric light is used, was asked if it spoiled the appearance of the "make-up," and said the same lights were in the dressing-rooms, and if an actor "made up" by the light he would look all right on the stage. The expense of putting in this light has been $15,000 to Manager Haverly, but he was determined to do away with gas, and he has done so. There is no doubt but that the light will be a great success, and every one is enthusiastic over it.

American Gas Light Journal
Oct 16 1882

ELECTRIC LIGHTING TEST FIZZLE.—And now comes the intelligence that another proposed test of the electric lighting apparatus of prominent companies has fizzled out. Our readers will remember that a test was proposed of the apparatus of the companies exhibiting at the Chicago Railway Exposition, which should have the value of the highest expert examination, and upon their award the medals should be given. A jury composed of Prof. Henry Morton, of Stevens Institute of Technology, Hoboken, N. J., Prof. B. F. Thomas, of the University of Missouri, Prof. Charles R. Cross, of the Massachusetts Institute of Technology, Boston, Mass., E. P. Lyon, Editor of the *American Machinist*, and Prof. James Dunton of Stevens Institute, was appointed to make such tests.

The companies signing an agreement to enter were the United States, the Thomson-Houston, the Fuller, and the Western Edison. The latter made its signing conditional upon the approval of the parent company, and this approval was not given for the reason, as the Edison Company states, that sufficient tests have already been made. The Brush Company refused to enter at the outset, and the Thomson-Houston Company states that they are too busy to go to the trouble and expense of such a test, and do not wish to spare Prof. Thomson for the purpose. We have not learned the reason of the Fuller Company.

Electrical World
Apr 21 1883

The seventeenth building of the Edison Electric Light Company is an interesting and complete exhibit of the surprising growth of the electric light in the short distance in the public favor all over the world of the Edison light in particular. The arrangement of the plants in this country are given in detail, including a description of plants for village lighting and in a good many newspaper offices. It is stated that in the first district of this city the company is lighting 306 houses, viz: for 247 lamps; it is also interesting to learn that the building of the Western Union Telegraph Company, Dey street, Broadway, is to be lighted from the Pearl street station by a special conductor running down John street, and connected with the net-work of conductors in the first district, at Nassau street. The building is being wired for 845 lamps, but for the present only about 285 will be used, distributed somewhat as follows: Associated Press room, 6; operating room 107; second floor 55; halls, 6; first floor, No. 3 Dey street, 15, and second floor, 30; third floor, 30; total 285 lamps. In England the Edison plants installed or in process of installation by the London company number 4,661, and by the Manchester company 5,000—a total of 9,448 plants. The company is also lighting the Holborn Viaduct, the first instance in that city of a public thoroughfare being lighted by incandescent electric lights. On the continent of Europe the machine works of M. Lobaziez, at Nantell, Spain, are now lighting 1,000 lights are now being made to light the depot and Post-Office at Stuttgart, Germany; while at Avignon, France, the Edison Company is just establishing a central station. At Ivry-sur-Seine the Edison factory is employing 200 workmen, and the portion of the factory which is devoted to the manufacture of lamps is turning out 400 lamps a day, to say nothing of dynamos and other apparatus. During the recent court ball at Vienna the imperial palace was also illuminated by the Edison light. In Cuba the office of the *Diario de la Marina* (newspaper), in Havana, is lighted by the Edison system, as are also several sugar estates on that island, while in South America several mills and private houses are lighted from the central station at Santiago, Chili. There is also an interesting account of the engine "Lawrence," which in March last performed the unprecedented feat of running at a speed of 350 revolutions per minute for 17 days without stopping—a number of revolutions which is a tremendous one, and would have been equal to a journey around the world. The last paragraph in the pamphlet serves to show to what perfection electric lighting apparatus has been brought, while the entire bulletin demonstrates the popularity of the Edison incandescent light.

Electric Lighting.—XXIII.

ARC LAMPS.

The problem of "feeding the carbons" in the production of the voltaic arc is one which has received even more study than that of generating electricity by means of dynamo-electric machines. From the year 1844, when M. Foucault brought out his erratic hand-regulator, to the present day, that field has fairly teemed with invention, as can be judged from the records of the patents granted in various countries for arc lamps. It is within the few years which have just elapsed, however, that the types and modifications of arc lamps have multiplied most wonderfully. Some inventors have also ventured to experiment on a dozen different kinds of arc lamps in this brief period, and in the multiplicity of kinds which prevails, all attempts to classify are lamps according to distinctive features that must necessarily be involved in confusion. These few years also mark the dawn of the industrial era of the dynamo-electric machine as well, and while the growth of invention or discovery, has similarly repeated itself in more than one instance. Not to go further, we can allude to the principle of automatic regulation of the length of the arc by the action of a shunt, or derived circuit, from the arc circuit itself, an improvement of much importance, as utility that we may consider the success of the arc light in industrial applications, to date from its introduction in the arc lamp. Several claimants came forward as the originators of this idea, and not less than three appear to have really conceived it and worked it independently, or at least about the same time, when all of a sudden a fourth among many others came forward as the discovery of claimants, who anticipated those by nearly a quarter of a century. Invention, construction or the adaptation of mechanical devices, these artificial lamps of ours, and sometimes the ingenious have been found in some of the most unexpected places, while the unexpected has also come to attract much attention, and which have long since passed into oblivion. There, may be found the germ of many a valuable idea which has perhaps again become current in the public mind, by the efforts of some later inventor, who conceived it anew, apparently without the slightest knowledge of its antecedent, for it is only within a couple of years that the history of the art has been accurately traced. . . . Many of these old ideas possessed more or less value, and show a large amount of inventive skill; they may look to us from our present perfection, and doubtless more than one of these pioneer electrical inventors would have received fame and fortune had he lived in the present era of electric lighting, and would have benefited from the present knowledge of the science.

As it was, in the main, the clock-work escapement, or governor or eccentric, the electric light was attended to with more attention by any other scheme than that of curiosity, for it was scarcely more than a curiosity of mechanism, and for lack of any arrangement one after the other of these ideas, many of which might have led to invention, the inventors were passed by and neglected, until they had become entirely forgotten. Some were to have been more particularly the case in England, where the electric light generally was attended to with more attention, strangely enough the number of inventions relating to the practical application of electricity to lighting, at the same time. In France the attention received more attention from physicists and chemists, and some of the types of regulators which were then devised received at least the benefit of a trial, and some few of them improvements were carried out—although a superior degree of perfection had been attained. Three lamps have been thus identified with the early days of the electric light, viz., Foucault's, Serrin's, and Dubosco's and, if we look at the question from its practical side, they are in fact about all that deserve mention in detail, for it is only since the advent of the Gramme machine, and of its various modifications, that the arc lamp can be said to have really entered on its career of development. All of the lamps which have come into use, the world over, have been produced since this period, and, in fact, within a few late years.

But, although these three lamps were about the only ones that received the sanction of practical use, it may be interesting to glean some brief reference to a few of the more original inventions. It would be superfluous to attempt to refer to all of these earlier ideas, since many of them do not possess much value, and, besides, the principles involved in the regulation of the arc can be well enough understood from the consideration of a few of the representing the space for the many modern types, which we will have occasion to refer to, as we take up each particular system in turn.

The first regulating mechanism appears to have been produced by one Thomas Wright, in England, in 1845. The device consisted in a series of discs touching each other at their circumference, and which were separated from mutual contact after the current had been established, the discs being rotated by clockwork. As a part of the discs formed one pole and the remainder formed the other pole, a small arc was established at the edge of the discs.

It need scarcely be said that the device is infinitely practical, and for reasons quite obvious. Even if the impossibility of keeping the discs from wearing unevenly could be removed, the shadows cast by the discs themselves would interpose too much light.

In 1847 Mr. W. E. Staite produced an arc lamp in which a clockwork mechanism acted on a thread around the circumference of the carbons. This lamp, although ingenious and ingenious, was not as practical as a single thread to the right distance for instance, had it been composed of too many turns of wire, it would have been difficult to pull the carbons far enough apart to break the arc before the weakening of the current in the general circuit, in consequence of the lengthening of the arc, would have caused the . . . attractive . . . sufficiently . . . to make a balance between it and the weight, while, . . . a two . . . weak solenoid, on the contrary, the action might have been insufficient to cause the separation

Brush Electric Light Companies" Convention.

As announced in the March 17 issue of THE OPERATOR AND ELECTRICAL WORLD, an important meeting of representatives of the various Brush electric light companies in different parts of the country was held at Cincinnati on the 10th instant, pursuant to a circular issued a few weeks ago. In this circular, which was issued by the S. W. Brush Electric Light and Power Co. of New Orleans, it was stated that the Brush sub-companies having given or contracted to give nearly one-half of their capital stock to the home company, for the privilege of using the inventions of Mr. Brush, find that although possibly the purchase of franchise may some time in the future prove a profitable investment, they cannot safely assume the burden by complying with the demands of the Brush Company, which expected the sub-companies to pay a large cash bonus for the right to use the Swan lamp. We have no guarantee, the circular goes on, "that the Swan lamp will always be the most desirable offered for sale. Another year may reveal a lamp every way as satisfactory as the Swan, the manufacturers of which will be satisfied to sell at a profit of 100 or 150 per cent., without asking the customer, in addition, the enormous royalty for the privilege of having. In the preface to the recent work on electric illumination, by James Dredge, he remarks:

"That some of the companies have a useful and profitable career before them is not open to question, but it is vitiful whether few, perhaps if any, of the patents thus are worth the money demanded and paid for them. In me cases because the invention has but small intrinsic erience, in others because its originality, and therefore validity of the patents protecting it, is open to question. All or nearly all cases, because with the rapid arch of invention in this direction, toward which so many ple minds are turned, progress is so constant and so uick, that whatever appears almost boundless in its ingeiosity and utility to-day, is rendered obsolete by an vention of greater ingenuity and wider usefulness to-morrow."

If we purchase a franchise, and have no protection gainst infringements, many soon come to have any value. Knowing these facts, several lighting companies ave refused to consider the proposition of the Swan Company, and have so notified them. The Swan Company ave made a large number of such a lamp. If Brush companies act in concert, the Swan Company must make ome concession as to a basis of fair profits on lamps, ome other payment for privilege of buying the same, r the Swan Company will not make fair terms with us. Brush companies act for you, to meet with us in the ity of Cincinnati, April 10, 1880, for the purpose of ecuring an understanding on terms to pursue, and so secure a oncert of action in this matter of common interest."

The following were among the delegates present, Brush companies being represented: Alexander Seitz and R. P. Orion, secretary, East Saginaw, Mich.; D. Howard Tuttle and David E. Evans, Baltimore, Md.; W. J. Port, Toledo; E. M. Avery, Cleveland; George O'Connor, New Orleans; C. M. Bullock, Chicago; S. E. Shelleville; J. L. Bayuer, Louisville; C. W. Hoskit, Memphis; S. A. Duncan and John E. Baldell, Pittsburgh; Superintendent Wolleslager, Cincinnati, O.; Samuel Hipp, Galveston, Texas.

The proceedings were not made public, but we learn that Mr. T. J. Montgomery, of New York, was present to represent the Swan Company, and seemed disposed, if possible, to arrange the matter to the satisfaction to the sub-companies. Other incandescent lamps were discussed, and the claim of the Maxim and Edison companies that any incandescent lamp other than their own infringes their patents, were also briefly considered and voted not worth considering. The common report that the parent company held or was seeking the control of the Swan light was not discussed, as it has been shown that its holdings of Swan stock were trifling as compared with its interest in the success of the Brush companies, forty-eight per cent. of whose stock it holds and to whom it expects, besides, to sell large numbers of storage batteries, which it manufactures.

The upshot of the discussion was that an agreement perfectly satisfactory to all parties—as was evident by the smiling countenances of all concerned on adjournment at midnight—was arrived at. The Swan light was adopted on terms which are not to be made public, and a permanent organization of the Brush Lighting companies was effected with the following officers:

President—M. C. Bullock, of Chicago.

First Vice-President—S. E. Bell, of Nashville.

Second Vice-President—F. P. Baker, of Topeka.

Secretary—J. P. Baldell, of Pittsburgh.

Treasurer—Lewis Sessongood, Cincinnati.

An executive committee of five, consisting of the first four officers named and Mr. Geo. O'Connor, of New Orleans, was also elected.

Mr. G. W. Stockley, vice-president of the parent company, at Cleveland, and holder of one-fifth of its stock, was present, and assisted at what seems to have been a happy settlement of affairs. The adjournment was to meet at the call of the executive committee.

Gen. Dan Sickles'old ally Edison Systems.—On the evening of April 16th, ex-President Diaz, of Mexico, with his wife and the members of his suite, were initiated to a limited extent into the mysteries of Edison's system of electric lighting. The party was conducted on its tour of observation by Thomas A. Edison and his assistant, Mr. F. Hastings, Secretary of the company, and Col. Sherman, who represents the company in South America. The first place visited was the house of Edison, No. 32, in John street, which is fitted with the Edison light. The house is one of the best residences in the city, and the record of its company is shown by a handsome library presented to the members by Goodwin & Co., for delivery shown in entering a building stored with powder and other explosives, at No. 208 Front street, July 18, 1860, and extinguishing a fire. There are the most automatic appliances, and in addition Mr. Edison has constructed an arrangement, by which an unknown with them by which the lights are turned on the instant the electric bell rings. When the visitors arrived Capt. Joseph F. McGill had the lights extinguished and his men were sent to the trunk-room on the second story. The quiet that pervaded the house was broken by the sounding of the electric bells. Lights were turned up, firemen came from their beats in the adjoining yards, and in four seconds, according to time kept by Gen. Diaz and his party, the horses were harnessed to the engines and were ready to start on a run. The exercise was repeated a half-dozen times, and each time was practiced with applause, in which Mrs. Diaz led. Gen. Diaz also joined in the cheering which greeted the performance, and expressed himself as much gratified, saying the performance surpassed those he had witnessed in Boston. After leaving the private house the party visited the First District works, in Pearl street, and then the machine shops in Goerck street, and Mr. Edison's laboratory, at Seventeenth street and Avenue A. Elaborate explanations were made by Col. Sherman, who is an old friend of Gen. Diaz, which were listened to with much apparent interest by the members of the party.

THE ELECTRIC LIGHT IN THE CITY.

WE gave on pp. 209 of Vol. XXXII. a short account of the experiment to be made in the City of London with the Electric light—an experiment which it is grounded will have an important effect on the progress of the "new" system of lighting. It will be remembered that one hundred were accepted from three companies working respectively the Brush, the Siemens, and the Jablochkoff systems; but only two of these have been carried out, an arrangement having been granted to the London Company who have taken up the contract for the Jablochkoff system. As we pointed out in the article referred to, the choice of the authorities might well have fallen upon any other system than the Jablochkoff, which has long been tried on the Thames Embankment, and though Crompton's is not substantially different, we may be satisfied that there will be no needless trial of an already well-tried system. The Brush system extends from the Surrey end of Blackfriars Bridge, along New Bridge-street, Ludgate, and the north side of St. Paul's Churchyard, to King-street, Cheapside, where it meets the Siemens system, which extends from the Guildhall along King-street, Cheapside, the Poultry, Bank, King William-street, to the Surrey side of London Bridge. The relative cost of the two systems is seen by the following figures:—

	Working.	Fixing.	Total.
Brush ...	£509 ...	£710 ...	£1,219
Siemens ...	2,779 ...	1,455 ...	4,234

The total cost of the other system which is to light the line from the Surrey side to the Guildhall, besides going down Queen Victoria-street to Blackfriars Bridge is to be £2,230 in the first days during which the experiment is to last. The Siemens lights are worked from a central station in Old Swan-lane, the Brush from a similar one in Bridge-street, Blackfriars, each with its separate steam-engine, and a third engine in reserve. The machinery supplies current for six powerful lights, carried high into the air on a mast at a height of 80ft., but so arranged that the lights can be lowered with ease, besides the 28 smaller lights, supported on iron standards, which are to be placed at the Government. The cabinets in all the lamps are fitted with copper, those in the large lights being 20in. long and 7½in. wide, and those in the smaller 14 inches long and 5½in. wide. The other lights being worked by alternating currents, the arcs are both of the same size, being 3mm. long by nearly 2mm. (12mm.) in diameter. As to the photometric results of the experiment, it is for the small lights 2000 candles; for the larger as much as 8000 candles. Each of the large lamps has its own dynamo machine, while the smaller lights are worked by two alternating current machines, each supplying 14 lamps in two groups of seven each—that is, the lamps are so arranged that they are alternately in the same group—an arrangement, which, in the event of anything going wrong with one set of lamps would still leave some of them alight on the line of street occupied. The lamps carried by the fifty-foot masts are hauled in position by the workmen in fitting the carbons and rest on a platform about 10ft. from the top of the ground. The cables are carried in trenches, the mains being made from iron box level with the pavement. The cables used are those well known as the Silvertown make, but their large conductivity and the very large insulation resistance, 100 megohms per mile, are specially noticeable. The cables are carried in iron pipes, and the connections are made in iron boxes, which are filled with a composition which will be found of a peculiarly useful nature. We shall no doubt be able to test the efficiency of the electric light in fog; the effects, if any, of lightning will be witnessed; and last, but not least, we shall learn whether the passage of powerful electric currents in the lighting cables has any inductive influence upon the telegraph and telephone wires which may happen to be in the vicinity. Finally, the cables being, already laid, it remains to be seen whether they cannot be used for other purposes in addition to the electric light, as, for instance, the carrying of telephonic messages, or the transmission of power to enable a small engine to work the dynamo machine. The lamps are all surmounted by shades, which are to be used when any fog prevails, in order to utilise those rays which would otherwise serve to illuminate the sky. London Bridge has nine of the smaller lamps, two at each end, and a more brilliantly illuminated than Blackfriars, which has seven only of the Brush lamps, now being placed at the Middlesex end. The longest circuit on the Siemens system is that supplying the large lamp in front of the Guildhall, which is 2,500 yards in total length; but the resistance does not exceed a Siemens unit, or a trifle less than one ohm. The lattice-pole near the north end of London Bridge is more than 120ft. high, its base being fixed in Thames-street. In this case the top has been stayed by fine wires attached to neighbouring buildings.

The Brush system, unlike the Siemens, is all conducted in one circuit, the current for the 32 lamps being generated in the Bridge-street station by two-street, Lambeth, which is a little to the west of Charing-cross railway bridge. Hence the cables pass along embankment, and through Whitehall Bridge to near the corner of King-street, Cheapside. The total length of the circuit is not much short of 7,000 yards, and the resistance is about 2 ohms. At present the current is supplied by two of the ordinary eight Brush machines, coupled in series; but it is intended, before long, to work the whole circuit with one machine, which will be driven by a Brotherhood engine on the same bed-plate. For several reasons the experiment with the Brush system is regarded with more interest, as when the doubtedly splendid results achieved by the Siemens Company; for, in the first place, the cost of working, £509 for the year, is not much more than one-quarter of the cost of gas-lamps which the electric light replaces, and has been stated that the company tendered at that price for the sake of the experiment, and that it would be prepared to change from gas to electricity is a decided improvement, and if that be obtainable at the same outlay of money, there can be no question as to the value of electricity as an illuminating agent for the public streets. In addition to the suggestion above referred to, we may mention that the Government and they will be able to show a profit in regular working, especially if the system is extended. In the second place, the lamps are of very powerful lights of 8000 candles by the ordinary standards, to which extensive have been tried in order to raise the lights to a height of 100ft. from the pavement. The lamps are, however, found to be not only capable of burning for 16 hours. Some of these are inclosed by clear glass globes, some by frosted glass, so that the effects of the lamps can be fairly tested. The arrangement of medium-power lamps, carried by comparatively low posts, is believed to be better adapted for the illumination of streets, than the use of very powerful lights at greater elevations; but whatever may be the result of the present experiments, the Brush machine has the advantage, that it can be used for varying either a number of lights of series or for producing a highly concentrated beam with one pair of carbons. Should the twenty days for which the experiment is to

THE VIENNA ELECTRICAL EXHIBITION.

(FROM OUR SPECIAL CORRESPONDENT)

Vienna, the third year in which a great International Electrical exhibition has been held, the first Exhibition in 1881 the labours of a few pioneers in the field of electric science were collected together, and an impulse was given to the further development of it. At Munich in 1882, and now at Vienna in 1883, the interest has increased, the progress which has been made during the last twelve months is very great indeed. It may say at the outset that I think there is much of interest yet there is little or novelty in the Exhibition. But the novelty is not in the Exhibition and the number of novelties are greater than at any previous show, for the reason being that the people in the Electric Supply have had no previous opportunity for testing what has been done in the practical application of electricity. An instance of the feeble light consists of three distinct parts—the source of power, the generator of electricity, and the electric lamps and other apparatus for using the electricity. These parts, such as conducting wires, galvanometers, switches, safety plugs, and so forth, are the details of the various machines. This was the first time that these parts were made by distinguished scientific men. From these tests we have learned that none of the devices proposed have led to any marked increase of electrical efficiency. Out of the host of modifications of the Siemens ring there are only two which stand out as improvements in a suitable way, and these two do so chiefly for their mechanical rather than their electrical merits. The first important fault of the Gramme ring is that mechanical fault of the Gramme ring is that it is unsound as a ring. The coils have been through which the spindle passes, and when the current of a single coil, or of a group of coils is broken by the brush, or handle, apparently of equal brilliancy, the whole ring tends to injure the ring. And this were only to make visible the darkness in the distant ring. Accordingly, should the brush fail, the one point of inferiority of the unsoundness in the ring, though upon that score not to be respected, expresses no opinion. The electrical qualities of the former to exhibit which its name would rather lead us to expect it possess in a high degree the quality of diffusion in which magnetic is unrivalled. It is very likely that means will speedily be devised to overcome the tendency of the electric light to flit during shadows, should that be found a troublesome defect. When our correspondent says that the electric light supplied by the Edison Company is such that one can work or read without being conscious that he is so occupied by using that splendid illuminant in its highest possible praise. The danger of electrical contact in the electric light is fortunately very well understood by the number of persons accepting for public favour. On the whole we may, therefore, hope that the day is not far when we may all read and work and walk the streets by the light afforded by the electric light, for, or, whatever it is, and forget that the source exists between us and the sun. Of course, I have spoken of the electric light which the machine is made. It is satisfactory to find that rules of thumb are being supplanted by accurate formulæ and scientific calculations. I ought to mention that the remarkable machine of Messrs. Siemens and Halske, called the unipolar machine, is not exhibited here. A contrary statement which has been made in England, is erroneous, and, it may prevent disappointments, I to assure to know, before leaving here that this machine will not have the opportunity of seeing that most interesting machine. I have little to say about the class of machines called alternate-current machines, of which the most notable examples in England are by Siemens, Ferranti and Thompson, and J. H. E. Gordon. There is a feature of this class by Gaus and Company rivalling in size the Gordon machine. Its total diameter is 10ft., the revolving part having a diameter of 6ft. It has a fine engine attached directly, to the spindle. There is nothing new in the principles of its construction, and it serves to feed only 1,200 incandescent lamps of 16 candles. Still it would make the latter too long and tedious work I to describe all the details of electric lamps, are and incandescent, which are shown here. As yet I have not seen no great novelty. The Brush Company has a new method of mounting incandescent lamps for street lighting, which is effective. A neaty flat disc of porcelain is supported horizontally by a bracket on a post, its slightly convex surface is grooved. In the centre is a hole through which the incandescent lamp protected by a glass cover descends. In this way a pleasing effect is produced. Siemter and Lamoier have two lighthouse lamps and, several of Swan's and Mandin's large lamps with lenses. There are some finely furnished rooms lighted by incandescent lamps and the lamps relief (sunlight) which are worthy of a visit. The United States Electric Light Company had two lion heads like signal posts, similar to those set up by Messrs. Siemens in the City. Each of these supports a globe with five sets of lamps, which, so says, and were of Viennese manufacture. They were blown down in the gale of Sept. 7, leaving a few fragments. The Austrian Government commission of experiments has to report upon 30 arc lights and eight systems of incandescent lamps.

In writing this letter my object has been to direct attention to the most interesting features of electric lighting in the exhibition, and I have not attempted to give any part of mine- lamps of the different exhibits. Consequently there are many names which I have not had occasion to mention equally deserving of credit with those which have served to illustrate my

London, 1883

The Edison Formula, Sept. 1883.

THE LIGHT OF THE FUTURE

Our special correspondent, who is consulting at the Northeast remote from an exhibition, says: "Undoubtedly the last Edison ever what he has seen and handled in connection with the exposition for lighting New York City with the Edison incandescent light. When a critic both sober-minded and competent is able to say with as much confidence, the time his come to congratulate ourselves and our readers that the days of gas, with their noxious fumes, and, in summer, uncomfortable heat, are drawing near thereof. It would be ungrateful, though, to pass up again that has done so good service for mankind at gas. Those that are old enough to remember the days of tallow candles and thereabouts by the gas jets will regard the latter, however, as a great boon, and should they live to see it superseded in turn. But the world moves, and there can be little doubt that the discovery of the method of lighting by gas will hereafter mark out stage of the ascent by which science is leading us up to the regions of perpetual day.

Our pioneers may always grow all you obviously discerned ideas in preceding articles of light that the least amongst these are the simplicity of the process by which it is made available so far as the user is concerned, and the economy with which it can be delivered to and utilized, and stolen. Perhaps the chief essential by means in the wonderful power of diffusion of light possessed by a very low degree of incandescence, expresses no opinion. The electrical qualities of the former to exhibit which its name would rather lead us to expect it possess in a high degree the quality of diffusion in which magnetic is unrivalled. It is very likely that means will speedily be devised to overcome the tendency of the electric light to flit during shadows, should that be found a troublesome defect. When our correspondent says that the electric light supplied by the Edison Company is such that one can work or read without being conscious that he is so occupied by using that splendid illuminant in its highest possible praise. The danger of electrical contact in the electric light is fortunately very well understood by the number of persons accepting for public favour. Evening Gazette,
CEDAR RAPIDS, IOWA., JAN. 6, 1883.

Amalgamation of the Edison and Swan Companies.—An extraordinary general meeting of the Swan United Electric Light Company (Limited) was held on Tuesday at the Westminster Palace Hotel, to consider the terms of an agreement about to be entered into between the Edison Electric Light Company, and a trustee on behalf of a company to be registered under the name of the Edison and Swan United Electric Light Company (Limited), "being a conditional agreement for the sale to the last-mentioned company of certain of the business, goodwill, patents, rights, privileges, and other property" of the Swan Company, and to empower the directors to take all necessary steps for carrying the agreement into effect. Mr. J. S. Forbes presided, and explained the position of the affairs of the company they suggested the possibility and the wisdom of bringing together the interests on the new and somewhat difficult enterprise they had become engaged, and there was a very large amount of feeling on the part of the shareholders as to the introduction of such a course. The directors had therefore carefully met the matter in view. He thought that both companies had acted prudently, before considering an amalgamation, in making to see what the terms would be upon which they would proceed under Acts of Parliament or provisional orders—steps at which, he said, they had now happily arrived. He hoped the wisdom of the principle of trading two interests like these and them would be admitted without much discussion. With regard to the terms, he had the satisfaction to present to them a resolution for considering whether the Edison Electric Light and the Swan Company had not a considerable price for the interest of the two companies, but over and above the Edison business the Swan Company had paid a considerable price for designs and original patents, and as the Edison Company did not present a similar asset, the Swan Company had reserved these patents from the agreement now under consideration. He moved the resolution, which was seconded by Mr. Swan, and after a brief discussion the resolution was carried unanimously.—An extraordinary general meeting of the Edison Electric Light Company (Limited) was also held on Tuesday, at the Gaiety Hotel, Mr. John Stewart in the chair, in the absence of Sir John Lubbock. It was considered advisable in the terms of an amalgamation with the Swan United Electric Light Company (Limited). After explaining the details of the proposed agreement, which entered the Electric Light Company to exercise the powers conferred upon it by the shareholders, the chairman proposed a resolution approving of the agreement submitted by the Board.—Mr. E. K. Blyth seconded the resolution, which was carried unanimously, observed that a great improvement in the success of electric lighting would be secured by the fusion of the two companies, as the Swan Company was practically the only dangerous competitor with the present company. The chairman stated that the company had been doing a fair business, the electric lighting business during the past year, the turnover during that period equalling that for the whole of the previous year, and during the first week of January, observed it might be interesting to know that the first ship in the world which had been entirely electrically equipped with the Edison system was the Guion Line Oregon, which was to sail on Saturday next. This vessel was fitted throughout by the Edison system.

The Edison Incandescent Light.

For some time reports have been current that Cedar Rapids was to be favored with an Edison System of Light plant, and we are now pleased to announce that the preliminary steps have been taken to that end. About a year ago a committee went from this city to Chicago to examine into the merits of the Edison system, and while they were much pleased with the light itself, it had not at that time been introduced under a central station into any town or city, and it was decided to postpone action. Since that time, however, results have been worked out and with a number of installations made in the eastern and New England states, which are now in successful operation. A few days since a meeting of the same gentlemen was held, and it was decided to secure an option for the franchise of this city, and to at once investigate the progress made during the past year. In order that the merits of the light might be definitely determined, Mr. Edison, at the request of these gentlemen, sent an expert electrical engineer, Mr. C. H. Cooke, who spent last week in making a careful survey of a proposed lighting plant, covering all of the business streets and all of the residence portion of the city north of Seventh avenue and west of Twelfth street. From the field notes and many estimates made, and with the number of lights required, rooms, etc., then this investigation has been conducted, it shall be found that this is a feasible enterprise in this city, and if so, a company will undoubtedly be formed and a plant installed.

This is a move in the right direction, and we trust that we shall soon have more light.

THE EDISON INCANDESCENT ELECTRIC LIGHT.

We give on this page illustrations and brief description of this valuable system of business and home lighting, which is being introduced very successfully throughout the States. These have companies already been formed in two of the cities of this State for the purpose of introducing this system into stores, public buildings, halls, churches and dwellings. This is evidently the coming light for domestic use; it being safe, economical, without heat and without danger, as it blackens and avoids the liabilities incident to other modes of electric lighting. This system is well worth the careful study and attention of our business men and of those who desire such a light in their business offices and houses. As Nashville is now starting on an era of reform and improvement and soon will have uniform time furnished by electricity, we trust such arrangements will be made

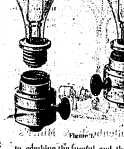

Figure 1.

to combine the fuse of the motive power, necessary to the use of this light, in the producer by introducing this neat, cool, safe and beautiful system of lighting the houses of Nashville the present and growing center of the new South.

There are two systems of electric lighting, namely, the Arc and the Incandescent. The arc is a light of great intensity, concentrated in one small spot, constantly changing in color, and very trying to the eyes. It is now used in streets and public buildings only. The incandescent is a small soft, steady, white light, of a brilliancy of 16 candle power gas jet of the best quality, and is especially adapted for domestic and industrial purposes. These systems of lighting are radically distinct, a fact which must be borne in mind when comparing the Edison incandescent system with the arc light.

The Edison Incandescent Lamp, of which Fig. 1 is an illustration, consists of a pear-shaped, glass globe about 44 inches in height, exhausted of air, into which is sealed a filament of carbonized bamboo slightly thicker than a human hair, which, when it becomes incandescent by the passage of the current, or electricity, through it, emits a beautiful, soft, white light, absolutely steady and constant, and entirely free from flickering or fluctuating. If desired, the illuminating power of a gas jet of the best quality.

The lamp is screwed into sockets, which are similar to those used in the ordinary gas fixtures, and is turned on or off by the same key. The lamp, when screwed into the socket, needs no further attention or care until the carbon burns out, when the old lamp is unscrewed from the socket and a new one screwed in, the work of a few seconds. The lamp may be left burning for hours which they will burn, but their average life, at 16 candle power, exceeds 600 hours of actual burning. Each light is entirely independent of the others and may be arranged and controlled singly, in pairs, or in groups of any desired number, and may be placed in any position whatever, inverted or otherwise.

The Edison lamp gives out but little heat (less than one-fifteenth as much as gas), may be grasped by the naked hand without inconvenience, is absolutely free from odor and poisonous or noxious gases, and neither heats nor vitiates the surrounding atmosphere. The most delicate fabrics are not exposed or injured by being wrapped around the lamp when burning. It is internally intensely. The lamp does not explode, and even if the glass is broken by any accident, the carbon is instantly consumed, and the light is put out and harmlessly. Besides being unequalled when delicacy, protected by the inclosed lamp, but the "current" is so introduced in the system that from any of the three sources above named, or from any source whatever, is absolutely impossible. The lamp is now in use in a large number of factories and dwellings, as no fire has ever taken place in the Edison system.

The light, besides being available for dwellings and factories, is also especially adapted to the lighting of steamboats. The cleanliness, absence of disagreeable odor, ventilation, freedom from danger by fire (no matches being required), and economy, make the light better for steamboats than any other known illuminant. The lamp has also been

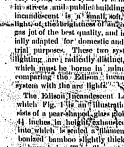

Figure 2.

found of the greatest value for the examination of ship's propelling machinery, as fully under water.

The lamp is also used for lighting mines. Mr. Edison has invented devices for protecting the lamp from breakage, even from the hardest handling, and for making the light absolutely safe from explosion or fire, even if the lamp should break in the damp.

The Edison system of power supply as well as light. By use of this dynamo, power may be transferred from a source of power to distant points for use, or from one portion of a factory to another. This invention affords not only the cheapest method, in many cases, of transferring power, but also facilities for minute subdivision and complete control. Among the many uses made of the electric power are the following: The running of lathes, printing presses, sewing machines, other small machines, elevators, and printing wafers. The current can also be applied for telephones, call bells and burglar alarms.

The Edison system for lighting large cities is modeled on the existing gas system. The current is generated at a central point, is distributed through subterranean conductors laid under the streets, connections are made with houses by means of branch conductors, and the current thus delivered, after passing through a meter in the cellar, which registers with perfect accuracy the quantity consumed, is then distributed over the house for use either for light or power. Houses are so wired that not only is light supplied, but by means of a device known as an electric motor power is also furnished for both industrial and domestic purposes.

The economy of the Edison incandescent light, as compared with gas, is beyond question, no matter whether the gas be used through the ordinary distribution system, as in cities, or is manufactured on the premises of the consumer by a portable gas machine. In estimating on the subject, the item of light in an hospital element to be considered, as the illuminating power of gas in different localities varies. The average of gas burner does not, even in best gas companies, give a light of over 12 candle power, so that in order to obtain the same amount of light as that given by the Edison standard lamp (16 candle power), a 7-foot gas

burner must be used. Even then, the whole light of the gas burner cannot be utilized in a work bench or desk, because it can neither be inverted or entirely locked by a shade, while, on the other hand, the whole 16 candle power of the Edison lamp is effective. Inasmuch as it may be inverted, or otherwise directed to any desired spot.

Assuming that "incandescent lamp" should be drive the dynamo is already present, the hourly cost of running 60 Edison lamps of 16 candle power each is as follows:

1 horse power 9 months of winter hour per horse power at $1 per	.12½
Depreciation on machines at 7 per	.01
Attendance, oil, etc.	.02
Interest on investment	.01
60 lamps, renewals, repairs per hour	.10
	.16½

The above lamps would replace the same number of gas jets, the hourly cost of which is as follows:

60 gas jets each burning 7 feet of gas per hour at $1 per 1,000 feet at 20 per cent.	.84
Interest on investment	.01
	.85

This shows a saving, by the use of the Edison light of 68 cents per hour of the Edison light, the cost of gas being more than four times as much as the Edison light.

Add to this pecuniary economy, the health influence of the light as compared with that of gas, its freedom from odor and from danger by fire, its steadiness, adaptability, completeness, and beauty

and there can be no doubt that the Ruhmkorff coil has immensely increased the range of electrical experiment, and has thus rendered it more valuable for scientific research.

The highest possible award obtainable at the recent Electrical Exposition at Paris was a Diploma of Honor, while that was higher than a gold medal." The juries awarded fifteen Diplomas of Honor and two gold medals. The full Congress affirmed this award, and gave to Edison exclusively a Diploma of Honor for an incandescent light.

Persons desirous of seeing this safe and beautiful system of lighting in practical use will find the National Manufacturing Co. (Cotton Mills) in North-west Nashville lighted thereby.

Figure 3.

THE GREAT DISCOVERIES OF ELECTRICITY.

L'Electricite: We extract the following few interesting passages in regard to the rapid progress made in electrical science, from a learned discourse pronounced on Dec. 16 last, by Prof. Ch. Maudrin, on the "Great Discoveries made in Physics since the End of the Eighteenth Century":

"Franklin was asked, precisely a hundred years ago, what ought to be thought of the balloons that the brothers Montgolfier had just invented. 'Can you foresee,' he answered, 'what will become of the child that has just been born?' This wise answer tells us that at the birth of a discovery we are unable to prognose the extent of the benefits that it has in reserve for us. Had any one foreseen, a few years after this answer, the importance that the invention of Volta's pile was going to acquire?

"This discovery of the finest instrument of modern physics, which marked the last year of the eighteenth century, was brought about by circumstances which, although generally known, it is proper to recall briefly in this place.

"Galvani, a professor of anatomy at Bologna, discovered in 1786 that the hind members of a frog, freshly prepared, underwent a contraction when a metallic arc established a communication between the muscles and lumbar nerves of the animal. Struck by so singular a fact, Galvani studied it, with all that sagacity with which his was endowed, in order to explain the phenomenon, which caused great sensation in the scientific world, he supposed the existence, in the nerves, of an animal electricity, or vital fluid, and presumed in likening its action in that of the electric pile—"that most marvelous instrument," says Arago, "that man ever invented, not excepting either the telescope or the steam engine."

Volta made his discovery known to Sir Joseph Banks, President of the Royal Society of London, in a letter dated at Como, March 20, 1800, and in another to Le Methérie, a French savant.

"The importance of Volta's invention was at once appreciated, and great honors were bestowed upon him, particularly by Bonaparte, who invited him, in 1801, to come to Paris, and who caused assisted at the meeting of the Academy at which the men of genius repeated the experiments that had been the starting points of his admirable invention.

"The discoveries of the decomposition of water, salts, and alkalies were made by means of the electricity of the pile, and were accomplished with a single liquid pile, which presents the great inconvenience of giving current whose intensity rapidly decreases. We must not forget that it was Bonaparte, again, who established the principles upon which is based the arrangement of the constant current pile, or those employing two liquids, and that it was in 1829 that he made known the first element of this kind. In the year following, in 1830, the English physicist, Daniell, invented the couple which bears his name, and which became a very practical apparatus. This invention obtained for its author the Copley medal. It is the predecessor of all those different kinds of electrical batteries we have at present, and that are applied in telegraphy, electro-metallurgy, and in a multitude of works that have made the pile so common an instrument in shops as well as valuable in laboratories.

"The letter from Volta to Sir Banks, which figures in the 'Philosophical Transactions' of 1800, is very lengthy, and is written in French. In it Volta describes, under the name of 'Artificial motive apparatus,' the ordinary instrument, and the Carrington-Bowes.

"The name of 'pile' given to Volta's apparatus soon prevailed, because the couples of the two metals are piled up vertically in its columns one on top of the other. Volta's invention is described in the *Journal de Physique* of the year 1800, under the name of 'electric pile' (vol. lvi, 1801).

"The letter to Le Methérie figures in the *Journal de Physique* of the same year.

"Volta was born at Como, on the 18th of February, 1745, and died at Como, March 5, 1827. His fellow citizens have erected a handsome monument to the inventor's memory, the place where he is buried is marked by one of the principal columns of the temple of Minerva, and a pile of Bolognian stone, in the honor of erecting a statue to Galvani, who immortalized his name by his great discovery. He died on May 4, 1798, one year before the invention of the pile, at Bologna, where he was born on Sept. 9, 1737.

"When Volta came to Paris, Bonaparte, who was a member of the Institute des Sciences de l'Institut, proposed that the latter should decree to the inventor a gold medal for his invention. The proposition was unanimously carried. The following year, the First Consul, who had presented Volta with a special gift from the State funds, created two pensions of 3,000 francs, for his experiment made during the course of each year on the nature of the fluid, and one of 6,000 francs, for the person who, through his experiments and researches, should succeed in decomposing galvanism as much as Franklin had done with lightning. Foreigners of all nations were admitted to the competition. The prizes were presented, in 1809, to Ermann, of Berlin, in 1806, to Davy, in 1807, and then to Biot, Gay-Lussac and Thenard in 1809.

"Napoleon the Third having in 1852 instituted a prize of 50,000 francs in favor of the author of the most useful applications of the Volta pile, the money after several competitions without result, was conferred in 1862 to Ruhmkorff for the invention of his induction coil.

"The foundation of the Volta prize having been maintained, it was decreed, in 1866, to Graham Bell, of Boston, for the invention of the telephone."

During the same year in which Volta announced his invention in England, Carlisle and Nicholson decomposed water by means of it. Also Alexander Cruikshank, who gave it the form of the trough battery, invented some salts, and W. Henry some acids. But it was the remarkable labors of Berzelius and Hisinger, in 1803, which, at this epoch, opened the new question of the decomposition of salts by the pile; by showing the law of the carriage of their elements to the electrodes. Davy made it still quicker by his method of the application of the pile to chemical decomposition, by inventing, in 1807, by the aid of a powerful pile, potassium, sodium, and other metals. In 1808, Berzelius and Pontin made their illustrious discovery of the amalgamation on the electric light that having been realized in 1837 by Foucaut, in terms of very great interest for keen investigation of calcined charcoal placed very close together.

"It was Faraday, who later on, toward 1832, established the basis of the laws of decomposition by current."

Berzelius, that celebrated Swedish chemist, was born on the 20th of August 1779, and died on the 7th of August, 1848, at Stockholm.

Davy was born at Penzance (Cornwall) on the 17th of December, 1778, and died at Geneva, on the 29th of May, 1829.

M. Gallepel, in a French chemical journal, asserts that copper can be inserted in all enamel and especially in wheat, so that when, upon analysis, bread is found to be charged with a certain amount of cupric salts, it must not be supposed, that such salts have been introduced for the purpose of making the bread whiter (said a suspicion has existed that bakers have used sulphate of copper for this purpose), but they must be regarded as natural ashiluents.

SHELBYVILLE NOTES.

To The Artisan:

Shelbyville, Tenn., Oct. 12, 1883.

I think you can indulge error in commenting on the correspondence about Shelbyville from our friends in Pittsburgh. Evidently South Pittsburg is our own State was meant, and not Pittsburgh, Pa., but I may be mistaken. (Which you are.—Ed.) Shelbyville has taken up the general movement of improvement and progress. Several new buildings have been erected, and others are in course of construction. Among the latter is a large addition to the woolen mills and the erection of a new factory for the manufacture of furniture, the capitalists, real, living at this late day, that the quality of the wool grown here is equal every foot here, ought, by rights, be manufactured right here.

The two woolen mills here are doing an immense business, running night and day, this county having more sheep than any other in the State, the mills are supplied with good wheat.

The shelbyville Mfg. Co. is rapidly coming to the front—is under full headway, turning out blankets in excellent style, having received large orders from the East and South for their wares where they now pronounced the best. Also a large lot of jeans, which is one of any grade is wanted is marked. A notice quite an accumulation of raw material on the yards, and yet the machinery shuts down (!!!).

Daily shipments of cotton goods from the splendid new "Sylvan Mills" are steadily increasing, showing a healthy state of business in that locality, but they are what everybody expected under the able management of Sully Shapard.

Yours truly,

THOS. TESS, Jr.

ELECTRICAL MATTERS.

A BUDGET OF NEWS AND NOTES CONCERNING THE DEVELOPMENT OF THE SCIENCE.

AMERICA'S ELECTRICAL EXHIBITION—AN EFFORT TO ENCOURAGE APPARATUS AND BY-HEIR THAT PROMISES TO BE IMPORTANT AND INTERESTING.

[Written for the Manufacturers' Gazette.]

The Electrical Exhibition, proposed to be held during the Fall of 1884, under the auspices of the Franklin Institute, at Philadelphia, is making considerable progress. The ground, fronting on the north side of Lancaster avenue, and extending from Thirty-second to Thirty-third street, the property of the Pennsylvania Railroad Company, has been leased to the Institute from Dec. 1, 1883, to Dec. 31, 1884, at a nominal figure. Col. Charles H. Banes, the chairman of the Electrical Exhibition Committee, thus states that the list of ground will give them a net exhibition space of 70,000 square feet. The treasury, department, 5 short time ago, provided the admission of articles intended for exhibition, duty free, under special regulations. On the part of the Institute it was agreed to raise a guarantee fund of $50,000 to be set apart for the contingencies of the occasion, and of this, $30,000 has been so far subscribed.

The most important work performed so far has been the formulation of sub-committees of the Institute, which have prepared rules and regulations for the government of the several classification of the various apparatus. The result that this arrangement of the exhibits is to be held will be greatly more instructive and comprehensive than either the Paris or Vienna electrical exhibitions. A table of the classification adopted and under the various articles thus over many subdivisions, which are numerous:

Sec. 1. Apparatus for the production of electricity.

Sec. 2. Electric conductors.

Sec. 3. Measurements.

Sec. 4. Applications of electricity.

A. Apparatus requiring comparatively small power.

B. Apparatus requiring large power.

Sec. 5. Terrestrial physics.

Sec. 6. Historical apparatus.

Sec. 7. Educational and biographical.

As may be judged from the above, the exhibition is intended to be exhaustive of present knowledge of electricity. Under the heading of apparatus for producing electricity are frictional machines, induction coils, Leyden jars and condensers, and a number of like character known as electro-motors; then follow electrical apparatus for producing voltaic electricity, or that produced by chemical action; then that produced by heat, or thermo-electricity; magneto-electric machines, used in blasting or exploding; then follow in great variety the machinery with which we are more familiar by common report, the dynamo-electricity, produced from electro-magnets, and largely used for illuminating purposes; these embrace arc and incandescent lighting apparatus; field magnets, armatures, commutators, brushes and all specific forms developed by the needs of the machinery in actual working. In addition, are mechanical motors, such as steam, gas, water, heat and wind engines. Of electrical conductors, the paraphernalia of telegraph wires and cables, electric light circuits, underground conduits, sub-marine cables and insulating materials will be shown. These items are but the inclusive heads of a long list of articles which illustrate the conductors of the electric current.

The section devoted to measurements is probably one of the most interesting to scientists, and the least known to the public at any of the displays. It is the purpose of the committee to make a notable and an, in not giving any medals or diplomas. The reports of the judges of each department will be given after the fashion of the days, and also, speed, force, energy, resistance, and any other points of the exhibit that may call for guess work. Instruments of precise measurement will be used by the committee of judges, and the conclusion reached will be a record of the judges. By a special arrangement with the treasury officers, instruments of precision as are not to be had in this country will be admitted free of duty, on the bond of the Institute being given that they will be kept for the sole use of the Institute at the exhibition. Under the section of the "application of electricity," the apparatus requiring small currents are divided from those requiring large currents. Thus, under small currents are all the legion of sound-transmitters and receivers, fire and burglar alarms, annunciators, clocks, registers, signalling machinery, medical and dental apparatus, and appliances of warfare, as torpedoes, gun signals and targets.

It arrangements can be made by the committee for an unbroken water front on the Schuylkill River, the submarine department of the United States Navy may make what would undoubtedly be one of the most attractive side features of the exhibition, to-wit: To place an electric light of 100,000 candle power in the bed of the river, and thereby illustrate the method used for discovering torpedoes or other engines of modern warfare under water in harbors and along coasts. Besides these apparatus are those for mining, for spinning and weaving; for pneumatic purposes; for writing and printing; electrical toys and miscellaneous applications too minor things. Among these revolving large currents are set forth electric illumination, and the appurtenances of the lighting, and electro-metallurgy, whereby coins for newspapers are rapidly produced, and electro-deposits of metals are made speedily and thoroughly on metals, pottery and textile materials, batteries and accumulators, and numbers of other things that the public rarely learn of. In terrestrial physics, the apparatus will be shown for measuring the electricity of the air, magnets of natural kinds and the apparatus used for weather signals.

This brief mention may outline the comprehensiveness of the exhibition. About 3000 circulars have been sent abroad, and about seventy-five applications for space have been filed, principally from Germany and France, and from some of the largest cities of those countries. The circulars for America will be sent out shortly, although applications are already in from some quarters in advance of the efforts of the committee. The purposes contemplated in this exhibition are, of course, principally educational. It is anticipated that schools and colleges from neighboring cities will take advantage of such an exhibit of electrical matters, as best to make excursions, that they may comprehend, by actual inspection, how far the science of its use has advanced, and thereby greatly enlarge their intelligence and facilitate their studies on the subject. There will doubtless be, during the exposition, lectures, scientific and intended for unscientific people, on the subject, methods and work of electricity, by those thoroughly competent to deal with the subject. These and many other features of interest promise to make the exhibition of enterprise worthy of the greatest energies of the association projecting it, as well as fully meriting the attention of American people.

NOVEL INCANDESCENCE—THE ELECTRICALLY LIGHTED CHRISTMAS TREE AT THE PORTER EXHIBITION.

The adaptability of the incandescent light for general illuminating purposes is well known, and its utility requires no justification; but all previous wonderful effects produced by the Edison system are eclipsed by its latest application, the lighting of the Christmas tree at the Foreign Exhibition. From whatever direction one enters Washington hall the attention is at once arrested by the sight of a very large pyramid shaped piece of evergreen, the lower branches having a diameter of twenty-five feet from tip to tip, rising forty-five feet into the air from the centre of the band stand in the middle of the floor, and covered with thousands of such things as red bronze cornucopias filled with candy, sugar plums, fruits, branches of silver and purple, red and blue, grapes, variegated glass balls, bells, and beads, dolls, etc., skeins of silver and golden threads trailing from the branches, while upwards of nineteen dozen small flags and bannerettes of all nations and numbers of Chinese lanterns and comic heads are artistically disposed over the tree, depending from the branches of which in all angles are red, white and blue glass balls of the Edison light. The railing, sheathing and balustrade of the band stand are tastefully festooned with unique designs in evergreen, the work of Mr. G. Chevalier. The stairway and floor are covered with cotton batting sprinkled with salts, which sparkles and glistens under the electric light with rare brilliancy, thoroughly conveying the idea of a frost like or snowy surface in the forest. Santa Claus fills the band leader's niche on the eastern side of the stand.

The following is the distribution of the 160 lights, which comprise 10 and 16 candle lamps: 46 whites, 32 lantorns, 14 comic heads, including caricatures of prominent citizens and others, "Humpty Dumpty," clowns and other grotesque figures, 12 reds, 24 blues, and the balance, embracing the three different colors, emerging from the centre floor and crowning the circular, frosted railing. The current which feed the lamps are brought from the dynamo room in the basement by mains which run into the circle under the band-stand, whence they radiate over the tree-trunk and branches by several flexible wires from a table, fitted with switches, "cut-outs," etc., two large main "cut-outs" governing all the lights on the five circuits, and three series of smaller cut-outs controlling eight lights apiece, the lamps being run in parallel circuits.

One switch governs the white lights, one

SEPTEMBER 6, 1882.

THE STANDARD.

DOMESTIC ELECTRIC LIGHTING.

(FROM OUR CORRESPONDENT.)

NEW YORK, TUESDAY NIGHT.

Mr. Edison's system of providing an incandescent electric light for domestic use in a given district has just been put to a practical test in the city. That district selected occupies an area of nearly a square mile. Only one source of supply is provided, and that the enormous illuminating power for sixteen thousand lamps, the electric current passing through eighteen miles of mains. The result is that the severest demands which the consumers have been able to make upon the new system have been satisfied.

The *New York Herald* is using in its business premises an isolated plant on the same principle; and the managers assure me that they are satisfied in respect to the commercial aspect of the question.

No new obstacle has presented itself to the success in practice of Mr. Edison's theory; and the public seem will be interested to know that this first practical experiment demonstrates the possibilities of the inventor's application of the multiple arc system, pure and simple, as distinguished from the series system, or the combination of the arc and series systems.

Throughout the entire district lighted as described each lamp was independent of all the others. Mr. Edison, who is President of the Commission of the British House of Commons, Dr. Siemens and Mr. Preece impossible to apply electricity for domestic lighting, from one source, over a great area unless it be upon quarter of a mile. Last night, although only five thousand lamps were lighted, they were distributed over the entire district of the square mile. In the district there are fifteen hundred consumers of gas, of whom eleven hundred have subscribed for the electric light.

THE PRESENT POSITION OF THE BRUSH COMPANIES.

The important interests involved, and the variety of rumours which have no sufficient reasons for our discussing the question in a special manner, holders, although we believe that few have been induced to part with their investments. This refers, of course, to the real investor and not to the speculator. As to the latter, it is impossible to predict what "bears" or "bulls" on the Stock Exchange may do, what means they may employ to achieve their ends, or what success may attend their machinations. To those who have carefully studied the question and who are able to judge of the validity of the patents possessed by the Brush companies, and of the excellence of their system as now perfected, the certainty exists that the bears will be cruelly caught in the end.

Before we enter more particularly into the controversies now going on we will pass briefly in review the results achieved by the Brush system of arc lighting. In the United States—its birthplace, its success has been marvellous, notwithstanding the competition of other prominent systems originating and competing in that country. The Brush lamp, being as near perfect as chiefly adopted to the lighting of streets and public places, as well as stations, large warehouses, shops, hotels, manufactories, etc., and is excellence for such purposes has ——— been declined. In April, 1881, there were in operation in the United States over 5,000 Brush lamps, of which 1,500 were used for street lighting. Since then the number has increased to an enormous extent, and indeed this system in the States seems to have carried all before it.

As to foreign countries, it may be stated that the Brush light has found its way to the most distant parts, that not only in France, Germany, Austria, and Spain, and other parts of the Continent, is it making rapid progress, but that it has already achieved success in many cities of South America, South Africa, Australasia, and especially in India and the East, where it is being most energetically developed.

We now come to the progress made in the United Kingdom. It is difficult to estimate the relative proportion of Brush lamps in use to those of other arc systems; but it has been stated to us that 40 out of every 50 arc lamps in regular work are Brush lamps. In the manufacturing districts in the North, especially in large iron works, the Brush system seems to have been established entirely adopted, and to have given the greatest satisfaction on account of its reliability and economy.

It has, however, been introduced into this country for only a comparatively short period. Indeed, in the commercial success we must turn, to the United States, where it has been longer in operation. There, during last month, the American Brush Company is stated to have sold no less than £600,000 worth of dynamo-machines and lamps, and to have on hand this year with some months' orders on hand; and the original 100 dollar shares of the company are now quoted at a thousand dollars each.

In incandescent lighting the subsidiary Brush companies have, until now, undoubtedly, remained in the background, as the Lane-Fox lamp, the licence for which they acquired through the parent company, the Anglo-American Brush Electric Corporation, had not been sufficiently perfected. This brings us on debated ground, the much talked of origin of exclusive use of these inventions. We confine ourselves to stating a few facts and leave our readers to form their own opinion. A licence is in existence of the Lane-Fox Incandescent Lamp to the British Electric Light Company, which was accompanied by an agreement made on the same day, under which the latter company bound itself not to use the name of "Lane-Fox" in any way with reference to this incandescent lamp, nor to do anything which would prejudice the rights of the Edison stations it is necessary, in order to regulate the light, that an attendant should continually and carefully watch the hand lamp and regulate the current by hand. Under the storage system it is possible to turn out part or all of the lamps, or to light them again without

---

the rod, one the 'size, one the batteries and one the cranks, heads, and as the currents are turned on and off in unison with music from the band on the grand stage, the action may hardly be termed piano-like, the whole operation being highly enchanting. Indeed, the resemblance to fairy land and scenes in the garden of the gouli is not remote, for, as the whirling carriages of the 'A' and 'B' sets enliven fields, lanterns and heads alternately flash to and out of the recesses of the tree, illuminating the dark green foliage, lighting up the fairy streamers, enlivening the expressive features of the "combs," bringing out the rich coloring of the lanterns, and evoking the snow, qualities of the glinting cotton and tinsel, the illusion is complete.

It is impossible to light this or any other tree with any illuminant other than the incandescent light, without danger of fire, for although gas might be pieced at the ends of branches in such a way as not to come in contact with adjacent limbs, the interior of the tree would be lighted, as often from the heat, and gas ignited, and the illumination, if it could be so completed fashion.

There is nothing like the illumination of this tree to present, upon the first display, to the public mind, such the Christmas tree of the Continental Exhibition, at the Hideout Conservatory, of New York, in its pattern of YULE SEASON.

The novelties and mechanical effects of the Foreign Exhibition tree were made under the immediate supervision of Mr. L. Bel-ringer of the parent company, an acknowledged expert in fancy electric lighting and fixtures, he having designed and had the charge of the Johnstown Electric Illumination Co., etc. Mr. Silsringer also had the charge of the Parent Company's improvements at the Centennial of the Louisville Exposition, where, 4000 incandescent lamps were operated. It is safe to say that no other electric light company could have undertaken, or could have carried out such a piece of work as continually surprised the curiosity and the admiration and appeals to the marvellous of the spectators of the Electric Exhibition. The arrangement and effects of this Aladdin-like Christmas tree. The Edison Company has scored many triumphs, but this latest achievement in electric lighting certainly surpasses all their previous efforts. The Electrical Ration Department has just reason to be proud of its work, Mr. Silsringer having been sent on here at its request. It is needless to say that this tree, which will remain until the close of the fair, and which is lighted daily at 7pm and 8.30 P. M., is a source of great attraction, and should not be missed.

Other than the lights of the tree, the decorations have been made under the superintendence of Mr. Alexander, who has evinced artistic qualities.

NEW RUSSIAN RAILWAY ELECTRIC LIGHT.

An exhibition of the Chesswright railway electric light took place a few days since at London. The novelty in this light is that it wholly dispenses with steam engine and furnace for its supply, and depends solely on the old voltaic battery, with certain novel combinations of elements. Six incandescent lamps of about 6 candle power each were supplied from a battery, of nine cells, and they gave an excellent, steady light. A number of gentlemen interested in the lighting of railway carriages, which is the leading object of the patentees, were present, and expressed decided satisfaction with the steadiness and brightness of the light and the extreme simplicity of the apparatus. It was stated that all right. On the table in front of him is a whose weight of the battery would not exceed 2½ hundredweight, easily carried beneath the vehicle, and that a single charge would last from twenty to twenty-five hours. The current can be switched on and off with ease, so as to light or extinguish all the lamps of a carriage, or if connected, of a whole train instantaneously. A single installation for a railway carriage would cost from £12 to £12 (£250 to £60), which is said to be not more than that of the first cost of gas. It is claimed further by Mr. Zelrath, the engineer in charge of the apparatus, that the elements employed can be sold after they have done duty in the battery as chemical compounds for almost as much value as they cost in the first instance, and that the price of working would be not more than that of gas, and for a superior light. This light is now experimenting upon by the Great Northern railway, and carriages are being fitted for it on the Southwestern and the Great Eastern lines.

SAFETY OF ACCUMULATORS.

Hugo G. Du Bois writes from Washington to the *Electrical World* as follows: From observation I have noticed that the general impression among those who are not familiar with accumulators, or secondary batteries, is that they were very dangerous things to apply. It was stated in one of our leading papers, the other day, that secondary batteries were unfit for commercial purposes, because of the great danger attending their use; that if any person should happen to touch one of the wires attached to them she should receive a severe shock. Having had seven months' practical experience with them, I can prove that, on the contrary, the secondary battery is the very embodiment of safety. I have worked around them in every possible manner, at times standing on the wet ground, my hands wet with sulphated water, handling the wires connected with the poles of a series of twenty or thirty cells, yet never have received a shock sufficient to give me the slightest injury. Just only the other day, to comfort was I of the safety of the secondary batteries, that I connected two wires, 10 electric light wires to a number of cells, which gave out an E. M. F. of about two volts; then taking the bare ends of these two wires placed them on either side of my tongue, and received no harm whatever. The sensation produced was about like that from a small Faradic battery.

LIMITED USE OF STEAM-ENGINES AT WORK.

Electricity has been applied abroad to lighting the interiors of steam boilers at work, so that the actual operation under given conditions can be seen. It is easy to understand, says the Mechanical Engineer, ... This will prove, in careful hands, a very great addition to our knowledge of what is taking place in boilers of certain types. Experiments made by competent parties would tend directly to economy of fuel, in that it could be seen by the condition and direction of currents whether the distribution of heat was uniform or whether it was irregular. The result of firing could be seen, as also the effect of opening the doors at certain periods: in short, the application of the electric light to boilers at work promises great results; but what action will be taken in this country regarding it remains to be seen.

TELEGRAPHING WITHOUT ARMS

At the school for telegraphy in Ann Arbor, Mich., one of the students has not the use of his arms, yet he sends and receives messages at the zenith of his power for indicting misery upon his fellow men! Somebody ought to invent an automatic dog which will smile approvingly at the gentleman who carefully closes the door but will take hold of the first who leaves it open and give him a good shaking.

It is very amusing to watch the little folks during the few days which precede Christmas. Their anger expectancy as to what they will receive is only equalled by the pleasure which they take in keeping the secret of what they are going to give. What a lot of surprises there will be Tuesday!

The Papyrus Club had a most brilliant "ladies' night" Saturday. Among the guests were Henry Irving, Miss Ellen Terry, Mrs. Frances Hodgson Burnett, Miss Louise Alcott, Miss Nora Perry, Mr. Henry Calne, Lodge, Rev. Brooke Herford and other well known in the literary world.

Illness are treated here, even seriously im-

ELECTRIC LIGHTING NOTES.

At the ordinary general meeting of the Crystal Palace Company, the chairman stated that they had purchased nearly sufficient plant to light the palace by electricity.

The electric lighting of the Thames Embankment is to be suspended for a few days for the purpose of replacing the former engines, lifferent situated in the wooden structure under the Charing Cross Railway bridge, by a new one.

We learn from an American contemporary that Mr. Montgomery contests the position for the Brush accumulary battery for the entire world outside the United States, and that he is preparing for an extended tour to establish agencies and effect sales.

The Maxim-Weston Electric Company, Limited, have, at the National Eisteddfod, at Cardiff, lighted the buildings and adjoining grounds in which the ceremonials and concerts were held. The building which has been erected by the Taff Vale Railway Company for locomotive sheds, and was lent by that company to the Eisteddfod Committee, was lighted by four Weston Universal arc lamps of three thousand candles each extended outside the building to the different approaches and grounds, as well as on the top and floor of the Taff Vale Railway. Thirty four lamps, each of one thousand candles, were used, dividing the huge circuits in the building into three, and driving one of the dynamos from an independent engine, the chances of total darkness, even for a moment, were reduced to almost all, but we are glad to be informed that the light during each night was most perfectly satisfactory, and the arrangements left little to be desired. The Fine Art Galleries were lighted by Maxim incandescence lamps of 50 candle power, driven off a Maxim machine; the lamps when driven up to its full candle power gives very pure light, which is particularly well adapted for pictures, and was very much admired by connoisseurs. The installation has also been used for the concerts, and for two dinners given to the engineers of the Taff Vale Railway, held in the same building.

Electric Light

George Grove

the slightest disturbance, thus greatly increasing the durability of the lamps.

The Brush high tension dynamo-machine will send the current many miles, and accumulators can therefore be charged from it at long distances. This arrangement has the further advantage that any power (for instance water power) can be used at the place where the machine is fixed. Two of the Brush self-exciting having the advantage of highly intelligent engineers,—Messrs. Brereton, Taylor, and King,—who have just succeeded in perfecting a system of incandescent lighting by means of improved lamps and accessories to which we referred already in last issue, and which comes very near perfection. The system is called the B. T. K. system, and from the different apparatus which we had an opportunity of inspecting, and the success of the installation already established, we must consider it a most important departure, and one which is likely to prove a source of great revenue to the companies.

With regard to the new dynamo-machines, of which so much has been lately made, it may be stated that neither the Ferranti, Sir William Thompson, nor the Gordon dynamo-machines, being alternating, can be used for charging accumulators, while it must be considered as an objection to large dynamos that to use them for direct incandescent lighting would be running great risks. If such a machine were to get out of order, a large number of lights would be suddenly extinguished. It would therefore be necessary to have a similar machine in reserve, which would have to be kept going at low pressure, so as to be ready for immediate use. Steam engines in duplicate would therefore also be necessary. We have not the slightest wish to depreciate, from the merits of the new dynamos, which may doubtless offer certain advantages; but we think that it is sufficiently proved that the Brush system properly developed and applied has nothing to fear from them.

We may further state that several of the Brush Companies are prepared to undertake the lighting of large districts or towns on the express stipulation that their maximum charge for are, as well as incandescent light, will not be higher than the present rate for gas, taking light for light—say at from 6d. to 6d. per thousand, while even the lower figure would leave a considerable profit to the Company. This statement has been most authoritatively made to us. That we are on the eve of a very large extension of the electric light in this country is certain, and few as yet realise the vastness of the field. All that is now required is that obstruction on the part of the local authorities should be removed. Once systems like the Brush obtain the licence for lighting large districts—and it is a fact that whatever the local authorities may do in some districts, the licence will be granted to the companies in a number of others—there can be no doubt of an unprecedented development of the electric light with proportionate profits to the companies. When once the operators on the Stock Exchange realise this fact considerable commotion may be expected. In the meanwhile shareholders in the Brush Companies will do well to keep their shares and bide their time. We feel assured that the result will amply repay them.

The Electric Light.

The leading questions upon this topic for over two years so far as New York city is concerned have been, "When are we to have the Edison Incandescent Lamps?" and "Why this delay?" To the first question we answer that by the first of August proximo that portion of the city bounded by Spruce, Nassau, Wall street and the East river will be ready. The second question may be fully and correctly answered by saying that as Mr. Edison never set a time for turning on the light, there has not as yet been any delay. Very few people have the remotest idea of the magnitude of the task Mr. Edison assumed, when he undertook to perfect a system that should give New York the best light of any city on the globe. That system is now perfected and the first district already described is practically ready for the greatest electrical triumph ever achieved. But little remains to be done; the street mains are all laid, the principal connections are all made, leaving little but testing to complete the conducting apparatus; the large engines and dynamo machines are in place together with their boilers of several thousand horse power awaiting the word, all ready, go! when a user on for New York city will begin, so soon to be followed by lighting the second district, which is already under way. This is reliable though not official.

THE MECHANICAL NEWS. AUGUST [illegible] 1882

THE GLASGOW NEWS—FRIDAY

AN INGENIOUS STORAGE BATTERY.

In December, 1881, Henry Sutton announced to the Royal Society of England that he had devised a storage battery, which consisted of a long strip of lead and another similar strip of sheet copper, separated by a layer of sheet rubber and wound together into a roll. This roll was placed in a glass jar four inches deep and four inches in diameter, and filled with a solution of sulphate of copper—common blue vitriol. The sheets of lead, copper and rubber were perforated to allow the free circulation of the liquid, and all crystals of the blue vitriol excluded from the solution. The copper being made the positive electrode, the solution, which is highly blue, loses its color. When the cell is fully charged the solution is colorless. During the discharge of the storage battery the solution assumes its original azure hue. This, cipange of color forms a beautiful means of telling when the cell is charged; it is a veritable charging gauge. The power of the battery is very great and very constant. It can be made to last for hours, time being dependent upon the quantity of sulphate of copper decomposed.

This form of battery was in turn improved upon by Charles E. Buell, of this city, who employed common lead sheet, coated with mercury, and placed in a porous cup. He put this cup in a glass cell and surrounded it with a coil of copper wire cloth which served as the positive electrode. The employment of sheet and wire cloth furnished the greatest surface in a given weight and constitutes a form most easily made.

FIG. 2.—THE CASE, AND END VIEW OF SAME.

Mr. Buell verifies the published statement of Mr. Sutton that a cell four inches high and four inches in diameter will keep a No. 28 iron wire at red heat for two hours; that it is more constant, and does not polarize during discharge, as does the Faure battery. It weighs very much less, occupies less space and costs less than the Faure battery of like force, and is unmanacled by patent rights.—[New Haven Register.

THE ELECTRIC LIGHT AT FAIRLEY.

The latest experiments of Mr. Archibald Denny, of Dumbarton, have just been wound up with perfect success. The electric light has been used for the purpose of testing the strength of armour plates, and the experiments have been carried out in the presence of a number of gentlemen connected with the Admiralty, the War Office, and the Navy, and also of a number of engineers and shipbuilders. The electric light was employed in connection with the Nordenfelt gun, which is capable of firing 40 shots per minute. The electric light was employed to illuminate the target, which was placed at a distance of 1,000 yards from the gun, and the experiments were carried out in the most satisfactory manner. The electric light was supplied by a dynamo machine of the Siemens type, which was driven by a 10-horse power engine. The machine was capable of giving a light of 1,000 candles, and it was found to be quite sufficient for the purpose required. The experiments were carried out in the most satisfactory manner, and the light

Manchester corporation, "is the whole of the city of Manchester." "Cursed with the burden of a granted power" would indeed be the words which the unfortunate corporation that was saddled with, such responsibility. It would become the prey of every electric light speculator in the country, nor would even the colossal profits of the corporation gasworks suffice to meet the expense of laying down installations on such an extended scale.

There is an element of unreality about the whole scene which becomes apparent when as the proposals of the companies and the counter-proposals of the corporations are closely examined. According to the rules laid down by the Board of Trade, the applicants for a provisional order must forward a memorial to the Department on or before the 21st of December, giving "a general description of the works" which are proposed to be executed, and specifying among other particulars what capital is proposed to be expended and employed in connection with the undertaking and the mode in which such capital is to be provided." As the Board of Trade intend rigorously to insist on that rule, most of the applications for a provisional order will be ruled out of court at once. According to Dr. Siemens's calculation, the installation necessary to supply a quarter of a square mile with the electric light will cost £1,177,000. Suppose that it only costs one half that sum, or £600,000; supposition—a very extravagant supposition—that no single installation exceeds a quarter of a mile in area. What corporation in the country has made any preparation for raising any such sum? It is not too much to say that hardly a single vestry or municipality has contemplated raising any capital for the purpose. They are applying for provisional orders solely to keep the companies out; and the only result of this gratuitous saddling of themselves with a most onerous and even ruinous obligation will be to the companies an open door in their own terms. But the companies are in an equally absurd plight. With a capital of fifteen millions they are proposing to execute works which would cost fifty. No provisional order can be granted except in cases where the applicants have given proof that they are able and willing to execute the work in a reasonable period. In numerous cases in many cases no such proof can be forthcoming. The companies are newly formed. Electrical engineering is only in its infancy. There are people the men not the money to carry out the proposals of electricity. It is much more likely that not a dozen provisional orders will be granted next session than that one-half of those now being applied for will be acted upon. The companies can well afford to wait. It is sound policy for them to hustle the corporations into the position of undertakers, for then they will have the municipalities at their mercy. At present the companies are at the mercy of the corporations, and we can only marvel that the latter, abandoning their position of vantage, should have fallen so blindly into the trap which was laid before their eyes. Possibly the Board of Trade will intervene to save them from themselves.

ELECTRIC LIGHTING PROJECTS FOR 1883.

THE Electric Lighting Act of this year has borne plentiful fruit in the shape of an immense multitude of applications for provisional orders, particulars of many of which occupy much of our space to-day. Hitherto the electric light has exerted itself in an experimental and frequentsey way. With really large schemes for the introduction of electricity as a public illuminant we are now making practically the first acquaintance. If the notices which are placed before the public to-day had appeared two or three years ago they would undoubtedly have produced another panic among the shareholders in gas companies. The experiments which cause the panic of 1825 were merely, to use Mr. Gladstone's famous simile on occasion, "like burning a farthing candle at Dover to show a light at Calais" in comparison with the gigantic schemes which are now being projected. To the alarmed imagination they amount to prospective the abolition of gas as a public illuminant. But the gas companies are not alarmed, nor have gas shares fallen in the market. If familiarity has not bred contempt, it has enabled them to recover confidence. The purveyors of the electric light, it must be admitted, are contributing to the confidence of the gas companies by the impracticable nature of their proposals. If all the schemes which are now on foot—at the instance both of local authorities and of the electric lighting companies—were to be carried out, a capital of, probably, £30,000,000 would be required, whereas the whole of the capital of the various electric light companies, exclusive of those whose business is with the Colonies and abroad, only amounts to about £1,800,000, of which, perhaps, one half has been called up.

The passing of the Electric Lighting Act has brought the screw companies into competition between the companies to a climax. Since the days when was caricatured in Professor Ayrton's story of the Glenmuckrikin Railway there has been nothing at all resembling the "splash" which has been made by the electric light companies during the last month or two. At the time for publishing the parliamentary notices has approached, there has been a gradual return to calmness and reason. Companies which had designed to apply for provisional orders in respect to every moderately sized town in England have decided to await further development, and other companies which had schemes for the lighting of the whole of the metropolis have determined to confine their efforts to two or three districts only. The provisions of the Electric Lighting Act stipulate that the projects of the electric light companies shall bear some reasonable proportion to the amount of their capital; and there is no the least likelihood that any company will obtain concessions the terms of which it cannot prove its ability to execute. The applications for provisional orders which will cover the whole of the lighting districts of the metropolis by some hundreds than they are at present if no stamp of the determination to get local boards, and parish vestries had not exhibited a determination to get or to keep the public lighting in their own hands. The City of London and the corporation of Birmingham have decided to make no application for licences or provisional orders, but to offer to grant licences to selected companies for the experimental lighting of given areas. These companies are the Swan United Company in London, the Brush Company, and the Jablochkoff Company, which has been followed by the vestry of St. George's, Hanover-square, and the local authorities of West Bromwich, Smethwick, Willenhall, Walsall, Wolverhampton, Rotherham, and Belfast. The town councils of Salford and Doncaster have contented themselves with a policy of direct opposition to the companies, without applying for powers to supply electricity themselves.

The antipathy of the great towns in the north have decided in favour of applying for provisional orders "in order to keep the companies out." Among those which have adopted this course are the London vestries of Kensington, Chelsea, and St. James's; Edinburgh, Glasgow, Newcastle, Liverpool, Manchester, Sheffield, Darlington, Stockton, West Hartlepool, Nottingham, Chesterfield, and Todmorden. Here (Brighton) the decision inclined to apply for a licence, and Grimsby has decided to proceed by private bill. It will not be possible to publish a complete list until the end of next week. Although most of the larger provincial towns are displaying readiness to adopt the electric light, if only in order to play the part of the dog in the manger, London will assuredly have the great bulk of experiments. The proposals of two or three of the companies cover almost the whole of the metropolis. As a rule, however, applications are confined to districts in which there are special advantages. Thus the parish which includes Regent-street is an object of most particular desire. The vestry of St. James's has received notices of application for provisional orders, or proposals to grant a lighting a licence, from no less than nine companies, among which are included three of the largest in existence. It is estimated that the lighting of the parish would cost £120,000, and among the applicants are companies whose capital is only £100,000. In many cases, however, it is proposed to raise local capital in the districts supplied, though it is obvious that a company, on showing what it proposed to expend, might obtain a concession without afterwards being able to raise the capital on which it had counted. No provisional orders, however, are likely to be issued on so slender a basis as the possibility of raising the needed capital in this fashion. As the licence can only be applied for with the concurrence of the local authority there is always a certainty that where this is granted a concession will be made, while, if it is refused, the same result would probably have followed on the expenditure of a couple of hundred pounds in the attempt to procure a provisional order. In many cases, however, the application for an order is absolutely necessary. Some of the districts proposed to be lighted intersect four or five parishes, for each of which a licence would be required, and, as London parishes seldom agree as to local works, the task of using all these one after another would be too much for the patience of any company that ever existed.

The parish of St. James's, which most of the companies had proposed to make a centre of operations, has determined on keeping the lighting in its own hands, and with that object is about to enter, or has already entered, into contracts with one of the larger electric light firms. The other proposals made for lighting the metropolis will be shown in the statement appended :—

METROPOLITAN BRUSH ELECTRIC LIGHT AND POWER COMPANY.

The Metropolitan Brush Company has a capital of £1,000,000, of which £500,000 has been issued in shares of £5 each. It has the supply of the Brush and Lontin patents for the cities of London and Westminster. It gives notice of application for provisional orders which will cover the whole of the leading thoroughfares of the metropolis. In the Paddington district it proposes to place lines "in, over, or along" all the chief streets and squares, including the Harrow and Edgware roads, Uxbridge-road, Kensington Palace-gardens, Westbourne-street, Pelesh-road, Hyde Park-square, and Hyde Park-gardens. The application for the district of St. George's, Hanover-square, confines the lines along Dublin-ground, and sides in Oxford-street, Regent-street, and Old Bond-street, continuing through Belgravia, down Vauxhall-bridge-road and Grosvenor-road to Victoria Bridge. A third notice of application covers the district between Oxford-street and the Albany in one direction and between Regent-street and Soho-square in the other. The other districts in respect to which the Metropolitan Brush Company proposes to make applications are—the St. Giles's-in-the-Fields, St. George's, Bloomsbury, and Holborn; St. Martin's-in-the-Fields and Westminster; Kensington; the Strand—including the Adelphi, Covent-garden Market and the Victoria Embankment; Chelsea, from Fulham-road to Brompton-road; Marylebone; Camden-town and Kentish Town, including Fernhill-Belsize-hill, and Clipham-rise; East London, including Sutton Dwellings, Newcastle, Commercial-road, Mile End-road, and the Stella Docks; Shoreditch and Islington through Highbury; and St. Pancras, in which are included such great thoroughfares as Euston-road, Tottenham-court-road, King's-cross-road, and Hampstead-road. The City, Clerkenwell, and St. Luke—that is, an area stretching from Hyde-park Corner to Upper Thames-street, and from Seven Dials to Blackfriars-bridge; Hackney, Edmonton, and Stoke Newington; Hornsey, Highgate, and Southgate; Tottenham; Acton and Ealing; Hampstead, Willesden, Hendon, and Finchley; Fulham; Chiswick, Battersea; Kensington, St. George the Martyr, and St. Saviour's; and Wandsworth and Wimbledon. The proposals of the Metropolitan Brush Company, in fact, enhance every part of London and the suburbs on which electric lighting, through the brightest prospect of becoming profitable, can be brought to bear.

THE EDISON ELECTRIC LIGHT COMPANY.

The Edison Company has a capital of £1,000,000, privately subscribed. It will compete for the lighting of the City, where it is already in possession. It will also apply for provisional orders covering some of the best of the London districts. Holborn viaduct is already lighted by the Edison Company; but the supply of electricity is to be increased by a new 1,200 light machine, which, it is stated, will be in operation before Christmas. This company proposes to establish a central station in High Holborn, the inhabitants being the large hotels and "public buildings." The company proposes to apply for provisional orders affecting the Strand district, Westminster, and the neighbourhood of the clubs, Kensington, and the region round Covent-garden Market. The Edison Company had proposed to apply for provisional orders for all provincial towns; but the Corporation may require it, as it has abandoned this project in favour of private negotiation with such corporate bodies as decide to keep the electric light under their own control.

SWAN UNITED ELECTRIC LIGHT COMPANY.

Like the Brush and Edison Companies, the Swan United has a capital of £1,000,000, £300,000 of which has been issued in £5 shares. This company has the Crompton and Gilt and the Swan incandescent lamps. It is confining its applications principally to the West-end, and more particularly to the districts round Hanover-square, the Strand, Victoria Station, and South Kensington. The area comprised in the applications in some cases includes portions of several parishes. The Swan Company is not at present applying for provisional orders for any provincial town or city, but is dealing privately with some of the corporations.

THE JABLOCHKOFF ELECTRIC LIGHT AND POWER COMPANY.

This company has a capital of £300,000, of which £150,000 has been issued in £5 shares. It is applying for licences in all the London parishes, and also in all the large provincial towns. It proposes to raise special capital for the carrying out of local contracts. By the Jablochkoff system the arc light can be used on the same circuit with the incandescent light.

FERRANTI, THOMPSON, AND ECE.

The capital of this company is £250,000. It entertained the idea of moving for provisional orders for all the London districts, but it has confined itself to asking for licences in two. These are the district of Chelsea, from the barracks along King's-road, and the Hampstead district, including Tonsley Park, Belsize Park, and Tyndale's-avenue. The company proposes to use a powerful incandescent lamp in the lighting of the streets, and to raise local capital in each of the districts lighted.

THE LONDON AND PROVINCIAL ELECTRIC LIGHT COMPANY.

This company has a capital of £200,000, in 40,000 shares, the whole of which have been issued. It proposes to make application for the lighting of the City, and also for the districts, "in and about" St. James's, St. Giles's, Bloomsbury, and Holborn.

WEST MIDDLESEX ELECTRIC LIGHTING COMPANY.

The West Middlesex Company has a capital of £100,000, in £1 shares, 50,000 of which have been issued. Some years ago it obtained a provisional order for the lighting of Hammersmith and Putney, but has not yet commenced operations. It has applied for a licence to the vestry of St. James's.

Although most of the companies named in the above list are the owners of patents for special varieties of the electric light, such of them as obtain concessions must be prepared to supply any kind of light that the consumer may desire, provided that it will not by its nature interfere with the general supply. A provisional order will empower the companies to supply and store electricity; to break up roads, streets, and public places; to interfere with sewers, watercourses, pipes, and telegraph and other wires; to purchase or take on lease any land that may be necessary; to make, hire, and sell all necessary lamps, machines, and fittings; to enter upon any buildings or premises necessary for the supply; and to collect rents and charges.

THE ELECTRIC COMPANIES AND THE METROPOLIS.

In London the districts affected and the companies which make applications connected therewith are briefly these :—

City, Clerkenwell, and St. Luke's	Brush, Jablochkoff.
Hackney, Bethnal-green, and Shoreditch	Brush, Jablochkoff.
Hornsey, Highgate, and Southgate	Brush, Jablochkoff.
Tottenham, Edmonton, and Leyton	Brush, Jablochkoff.
West Ham, East Ham, and Wanstead	Brush, Jablochkoff.
Fulham, Chiswick, Acton, and Ealing	Brush, Jablochkoff.
Hampstead, Willesden, Hendon, and Finchley	Brush, Jablochkoff.
Thornsbury and Rotherhithe	Brush, Jablochkoff.
Kensington, St. George's, and St. Saviour's	Brush, Jablochkoff.
Battersea and Wimbledon	Brush, Jablochkoff.
Camberwell and Penge	Brush, Jablochkoff.
Lambeth	Brush, Jablochkoff.
East London	Brush, Jablochkoff.
Lewisham and Lewisham	Brush, Jablochkoff.
St. Pancras	Pilsen Jost, Brush, Jablochkoff.
Paddington	Brush, Jablochkoff.
St. George's, Hanover-square	Edison, Swan, Brush, Jablochkoff.
St. George's, Bloomsbury	Brush, Jablochkoff.
St Anne, Soho	Brush, Jablochkoff.
St. Giles's-in-the-Fields	Pilsen Jost, Brush, Jablochkoff.
St. George, Bloomsbury	Brush, Jablochkoff.
St. Martin's-in-the-Fields	Brush, Jablochkoff.
Westminster	Edison, Swan, Brush, Jablochkoff.
Kensington	Edison, Swan, Brush, Jablochkoff.
Strand	Edison, Swan, Brush, Jablochkoff.
Chelsea	Ferranti, Thompson, and Ince, Brush, Jablochkoff.
Marylebone	Brush, Jablochkoff.
Holborn Viaduct	Edison, Pilsen Jost, Brush, Jablochkoff.
Hampstead	Ferranti, Thompson, and Ince.
Hammersmith and Putney	West Middlesex.

THE FULLER ELECTRIC LIGHT.

[SEE ILLUSTRATIONS ON PAGE 2.]

The development of the art of electric lighting is advancing to a greater extent, perhaps, than any other feature of the industrial progress of the age, the thought, skill and persevering effort of inventors, manufactory we have illustrated on the second page of this issue, is one of the pioneers in this field, and has brought the processes and appliances of electric illumination to a high degree of perfection. It was originally incorporated for the purpose of introducing the patents of Mr. J. B. Fuller, whose name it still bears; and after the death of Mr. Fuller, in 1870, it continued the work already begun, extending its researches and experiments and combining new patents with those already held, until the present complete result was attained. The company is now proprietor of the Fuller, Wood, Keith and Holcomb patents, and is a member of the Gramme Association.

Their improved Gramme Dynamo-Electric Generator, as now constructed, fully meets the severest tests to which such machines can be subjected. Its frame consists of the cast-iron side-plates, which are connected by the bars, or field-of-force magnets. To those magnets the poles, which almost entirely enclose the armature, are bolted, and are rigidly connected with each other by non-magnetic composition plates, thus preventing vibration or change of position of the poles. By this construction of the frame the greatest possible amount of magnetic force is attained. The armature, in which the electric current is generated, is a soft iron wire ring, closely covered with coils of insulated copper wire, firmly secured to its hub by a series of keys. The collector, commonly called the commutator, is composed of narrow copper sections, insulated from each other, and mechanically so arranged that any section can be removed without changing any other part of the machine. The brushes are narrow strips of copper, held in position by a brush-holder which prevents them from vibrating, and holds them in contact with the collector by a screw attachment. The current regulator is attached to an index-wheel on the front end of the frame. By setting this wheel upon its graduated scale, the number of lights desired are provided with the requisite current. Any less number than the maximum capacity of the generator may thus be maintained in operation, reducing the power required to drive it according to the number of lights in use.

The generators are constructed of all dimensions, and require but little care. Any of the parts can be readily replaced, as they are so made as to be interchangeable, and the construction is so perfect that no liability of derangement exists in their ordinary use.

The single lamp consists of a hollow suspending rod, a cylinder containing the mechanism for regulating the movement of the positive carbon pencils, a frame between the side-bars of which the carbon pencils are placed (as also the globe and shade when they are used), and the bottom plate which contains the negative carbon-holder. The automatic duplex carbon lamp is of similar construction, except that there are two suspending tubes, and two sets of carbon-holders are operated, changing the electric current automatically from one to the other when required. The carbons are 7-16th inch diameter. The single lamp—used also as a serial lamp where two or more lights are required in the same circuit—will burn from seven to eight hours. In the duplex lamp, when one set of carbons is consumed another set is automatically ignited, without cessation or diminution of light, and the duration is from fourteen to sixteen hours.

By means of an automatic cut-out, attached to both single and duplex lamps, any injury from accident or the defective operation of one lamp in a series is prevented from extending to the other lamps in the same series.

The Focusing Lamp is so constructed as to maintain the burning point of the carbons always in the same focus, and is especially designed to be used with a reflector or projector. Both carbons are fed with a positive motion, and not by cords or chains, and an adjustment at the base prevents any troublesome result, in case either of the carbons should burn faster than in the proper proportion. This lamp operates perfectly in series with both single and duplex standard lamps. With all lamps a hand-switch is provided for cutting the lamp out of circuit while replacing carbons, or in case the light is not required.

The usual size of the lights is 2,000 candle-power (nominal), but lights of much greater illuminating power are furnished when required.

The day has gone by when any argument was needed in favor of the adoption of the electric light. It is making its own way and demonstrating its economy in cost, its immense advantage in brilliancy and purity, and its freedom from unwholesome effects upon the air or injury to the eyes. For the illumination of streets and squares, and the interiors of large buildings, it is the only agent known, unless we choose to remain in the twilight of the past. Of the especial merit of the lamps and apparatus furnished by the Fuller Electrical Company, the best proof is the extent to which they are used. Their lights have been adopted in Brooklyn, Buffalo and Troy, N. Y.; in Hartford, Springfield, Providence, Philadelphia, Chicago, Washington, and various other cities. In the city of New York they are in use in numerous localities, among which are the spacious saleserooms of the Wheeler and Wilson Sewing Machine Co., Messrs. Lord & Taylor's Grand Street store and Broadway warehouse, the office of the U. S. Express Co., and the dock of the Old Dominion Steamship Co.

The New York offices of the Fuller Electrical Company are at No. 44 East Fourteenth Street. Mr. A. B. Chandler is the President and Mr. H. Seymour Geary Vice-President, Secretary and Treasurer. Mr. James J. Wood, inventor of the Wood Patent Lamp, and numerous other valuable improvements in connection with the art, is the mechanical engineer and electrician.

INCANDESCENT LIGHT.

THE EDISON COMPANY PREPARING FOR AN EVANSVILLE PLANT.

A Special Agent of the Company in the City—What the Company Is Doing Elsewhere, and What It Proposes to Do in Evansville.

Mr. Wm. F. Brewster, special agent of the Edison electric light company, of New York, is in the city to perfect arrangements for the introduction of the incandescent system of lighting in Evansville. Mr. Brewster has visited nearly all the cities where the Edison company has introduced its system of lighting, and has completed arrangements for the introduction of the light here. He has been in Louisville, Indianapolis, Kansas City and several smaller cities. Altogether the Edison company is now negotiating with responsible local organizations in twenty-four cities, including Evansville, and new organizations are being created and introduced almost daily. The company has within the last few months taken steps to put the Edison central system of lighting in Boston, St. Louis and Kansas City, and is now digging on Louisville, where a very strong company has been organized. Nashville, N. C., on the Pennsylvania railroad has a central system and is already lighted by means of incandescent lamps of ten candle power three lamps being on each post, and the posts being three hundred feet apart. This is the only city in the country, the streets of which are lighted entirely and satisfactorily lighted by electricity. Arrangements are now being made for similarly lighting Hamilton, Ont., near Orange, N. J., a large section of New York city is now lighted by means of these lamps, the light giving perfect satisfaction. The plant for this city cost six hundred thousand dollars, and could now be duplicated for considerably less than half that sum, the original plant having been an experiment and the system having been greatly simplified since then. There are two systems of wiring a city employed by the Edison company, the overhead wire and the underground electric tubing, the latter being in use in New York city and all other large places. That is the system it is also proposed to introduce here.

In Evansville there has been a thorough canvass of twenty-five blocks, including that portion of the city bounded by the river, between Fifth and Chestnut streets, and twenty-six more blocks are now being gone over, including First, Second and Third streets, so far as as Bayless. From this it is expected that a pretty accurate estimate can be made of the size of the plant that will be required here.

Mr. Brewster, in conversation with a JOURNAL representative last night gave quite enthusiastic talk speaking of the affairs of the Edison company. He says that until recently it has been the policy of Mr. Edison rather to perfect the system and to demonstrate its merits in a few central points, than to attempt to head off the speculators in the country at large. The system has now been brought to such a state of perfection, however, that the applications for the introduction of the light, which have for years been pouring in upon the company are receiving attention in the order of their receipt, and the result is that every block there is now a city in the east, and in the west, and south, will soon have the system in full operation. Mr. Brewster declares that the light can, on an average, be furnished cheaper than gas, and, where a large number of lights are required for fixed places as hotels, theatres, factories &c., even cheaper, upon an average.

Mr. Brewster, in answering all objections to the Edison incandescent light, says that the Edison system is the only one that is absolutely safe, and absolutely free from danger from fire. "You can," said the gentleman, "run your feet impunity break one of the incandescent lamps in a keg of powder, and the moment the glass is broken the light is out." He mentioned that during a recent visit to Chicago several experiments had been made with wirings selected with coal oil, the oil being thrown upon their midst without igniting them. Another advantage is the absence of heat. Burning in a vacuum, the lights consume no oxygen, and do not vitiate the air, and another point of importance to housekeepers is, that there is no smoke to soil pictures, curtains, furniture, etc.

Mr. Brewster was not disposed to discuss the merits of any of the other systems of electric lighting, but, in answer to direct questions by the reporter acknowledged that the so-called "arc" lights and candle power are "lamps are a delusion and a snare." He says these figures are obtained by means of what is called the Foreh standard, the light being five hundred candle power each the arcs in the four different directions running to the five hundred candle power each. There are no arc lights of one hundred candle power, as the statements to the contrary notwithstanding.

The operation of the Edison company have thus far been confined chiefly to, not wholly, to indoor lighting, for which it is peculiarly adapted; but for street lighting it is already demonstrated and in case, and Mr. Brewster thinks the public will very soon come to understand that for outdoor purposes the incandescent is very much superior to the arc system of lighting. In addition to being a steadier light, and it is, under the street-post system, much better diffused, and consequently more satisfactory.

Mr. Brewster will remain here several days in order to get matters into proper working order, and says that he desires the public to understand that when the company begins work here it will be upon a strictly commercial basis.

COTTON, WOOL AND IRON

AND BOSTON JOURNAL OF COMMERCE.

VOL. 21.—NO. 1. SATURDAY, OCTOBER 21, 1882. PRICE SIX CENTS.

THE EDISON SYSTEM OF ISOLATED LIGHTING.

When the writer of this was running the reportorial quill on a daily paper in New York city, some three years since, he was detailed more than once to visit the "Wizard of Menlo Park," and had pleasant interviews with him. He has also lived to see the vision, which has been heaped upon Mr. Edison's head—by a set of know-nothing journalists, who, unless they are sensationalists are nothing, and as sensationalists are very reluctantly turned into admiration of his merit and acknowledgment of his complete triumph.

The rapid strides made in electric lighting has been a matter of astonishment. It is safe to say that no man more than Thomas A. Edison has achieved success, or what is more satisfying to manufacturers, has achieved so signal a success that the electric light of to-day is free from the incidentals that have always attended gas and the accidentals that are in too close fellowship with kerosene oil. The Edison light is as far superior to any other light for manufacturing purposes as first-class kerosene is to moonlight. This is our own private expression. We have looked with much interest at the adoption of the electric light; we have seen it in the old world and the new; and it is only after some months of careful investigation with respect to its adoption by the manufacturing interests—and by manufacturing we mean mechanical as well as textile—that we are rather proud to say that the Edison light of to-day is the light, in its perfection for in advance of any and all others.

The Edison light is unlike any other electric light, and after Mr. Edison had thoroughly studied all that related to electric lighting, the circumstances under which it must be used, the purposes for which and the place in which, instead of pirating the inventions of others, making up arrangements which should neither be one nor the other make a system or invention, he made a most radical departure from any one who had preceded him, and invented a system of lights and all the appliances which were necessary to make that system successful and capable of adoption. This, as a matter of course, required time. How successful he has been, only those who have been most closely connected with him during all this work, can say.

It is true that during the time and through the delays caused by lengthy experiments he has been looked by the press, and in those who laugh last laugh longest, so Mr. Edison can afford to forgive those people for their ignorance, from the fact that he now offers the only thoroughly practical isolated light, and the only light that is completely applicable to the manufacturing or mechanical establishments where a natural light, such that does not glare in the eye, and one which is not more of a nuisance than a help, is demanded; where a light has a natural and pleasant yellow rather than the pale, ghastly white; where a light of small candle power, like eight to twenty-candle power, is furnished without that peculiar and almost intolerable flicker, jumpiness which, as we whatever term may be applied. While he has accomplished all this, he has also retained and embodied most important and essential qualities—that of proportionality his power to the light required, so that one, two, three, or more, the rooms of a large establishment can be lighted perfectly; and it is only a matter of momentary attention to graduate the power of the current to the work required; and if, on the other hand, only a portion of the work is required, it can be shut at a moment both to diminish the volume of the current and the work of the engine, with a steady that nothing approaching to incandescent adjustment of the regulation of a flow watch. Edison's points will all be considered by a Yankee manufacturer.

Mr. Edison has also accomplished other and important changes which are set forth further on in this article. He has accomplished also by his unassailing contempt for previously acknowledged laws in relation to electricity, he has ignored old and adopted standards, which had been held to be the only correct ones, and he has adopted standards of his own, seeking for himself laws in relation to electricity as he found them, the basis or the formulæ which he has established. He has proved that he can produce a current with the same energy as a "motor," and that he has accomplished the task which he set himself, namely, adapting the two greatest practical forces, steam and electricity, either his genius or those who believe in sensational. In a business manner with the two forces.

We have sought, in this article to avoid all theory, to confine ourselves to statements of fact, and these facts to such as shall interest our readers who have a wish to obtain the most authentic information in reference to this new child of invention, with a view to its adoption into their family. It is not a matter whether these families are large or small. Some of our manufacturing concerns have discarded one to two thousand gas burners, and introduced seven to nine hundred Edison isolated lights, and we shall soon show what these lights are doing by facts taken from the current expenses' sheets of these institutions. We are promised these facts and we shall very shortly give them publicity.

We have sought, in this article, to discard all biased statements of comparisons, and to confine ourselves simply and purely to fact, and we beseak from our readers careful attention where figures are given. Those who have not, should by all means visit the New England Manufacturers and Mechanics' Institute, where the several systems are now to be seen, on each of the days of the week, in full operation, and where any man, with good average ability, can make his own comparisons and deductions, with perfect satisfaction to himself, from a basis of business which is the only tangible or satisfactory one.

In the Edison system no are lights are used, the originators of that system believing that for the same power expended at the engine, or wheel, small lights, distributed over a given space, would give a far more effective illumination; for, by the former system (the are) with one large center of light, illuminating a large space, shadows must inevitably ensue. Edison uses what is known as an *incandescent* lamp, in which there are no moving parts and no mechanism; the light, therefore, is absolutely steady, provided the power is so. This lamp consists of a very fine platina thread, some nine inches in length. Within is the "carbon" about the size of and resembling a lamp-black, but in the shape of the letter U. This carbon is made of bamboo fiber (or was when the writer was there) which has been removed and is nearly pure carbon. This carbon is fastened to a small copper wire by bending the wire like a clamp about the carbon ends, and, to secure contact is rendered still more perfect by electroplating. This is known as the "carbon." In the manufacture of platinum wire, not more than a foot in length, and, to secure contact in the most perfect manner, a platinum wire is used, as also the same as that of glass, and consequently the two spread equally; therefore, the glass is not broken and the vacuum mentioned below is maintained. The base of the lamp is made of plaster of paris. At its bottom is a brass plate, which forms one of the "leading in" wires, and to which one of the "leading in" wires is soldered. The second brass plate which is pressed into the plaster, as in the base of the lamp, into the form of a screw. This forms the other "leading in" wire. The air is now exhausted from the globe until a practically perfect vacuum is obtained. The light is produced by the current passing from the battery, plates placed over the carbon to the second plate. As the carbon is of very high resistance, the mechanical energy furnished by the engine or water wheel is transformed first into electrical energy, and then into the energy of heat. Below is given (Fig. 1), a cut of the lamp. A represents the glass globe, B the carbon, C the plaster base, D one terminal, and E the other terminal. The average life of these is guaranteed to be at least 600 hours. In the same figure, and immediately below the cut of the lamp, is represented the socket. G is a plate fitted to receive the plug. Below cut of sight is diagram 2, which is a plate, T, insulated from first, on which rests the plate, E. The socket is attached to the ceiling (in the machine shop and workshops) by means of a 4 inch pipe, which screws into the base as H. The cap screw has also a hole inside of this pipe, one being attached to the plate, G, and the other by means of a small lead wire to plate, F. This lead wire serves as a safety guard; for since lead has about thirteen times the resistance of copper, if any short circuit or excess is accidentally produced, thus setting up an extra current, the lead will melt and the circuit be broken (stopping the flow at once) before the copper is heated. The key, K, serves as a break in circuit at pleasure, the "extinguishing" of the light. Each lamp is thus entirely independent of all others and can be turned on or off at will. Fig. 2 shows the lamp in position in the socket, being secured in same by means of the screw threads, I. The lamp can be used in any position, but in industrial work it is usually placed with the globe down as a screen of a metal or porcelain shade, attached to the ceiling (in the lamp, all the light is reflected on to the work in hand, and is used the same as a projection in the lamp. If it is desired, however, to use the lamp in any position can be readily changed, arranging this by means of a screw, which is also provided as shown in Fig. 2. These brackets are made in various forms, and are attached to the ceiling as mentioned above. As the circuit is metallically united on the system and lamp is made through brass in the box A, and not by the ground, as shown in Fig. 3, there is no danger of breaking this circuit by turning off a lamp. This can be required indefinitely. At the junction of the leg wires with the mains carrying the current from the generating machine, represented in Fig. 4. This consists of two parts, the base, A, and the plug, B. The main wires are led through the grooves, C, and the leg wires through the grooves, D. At the base of the plug is a plate, A, while the other, B, is the ceiling, in the plug, B, and, as in the base of the lamp, into the form of a screw. These are connected by means of a lead wire, C. When the plug is screwed into the block, A rests upon O, and D upon E. The current enters at S, passes through the lead wire to O, thence by the tap wire to lamp and back to main at X. This safety catch serves an analogous purpose to the automatic sprinkler in a factory. In the latter case, an abnormal heat melts the fusible metal, thus allowing the water to flow; in the safety catch, an increased current melts the lead wire for the reason mentioned above, thus breaking the circuit. This current might otherwise momentarily heat the copper wires. This device is a distinctive and noteworthy feature in the Edison system. As the system is always installed by competent men, the short circuit can scarcely occur, by accident, but in that event the safety catch is on the alert to provide an instantaneous and effectual remedy. In a factory or other large building where it is desirable to have an approximate whereby a number of lamps may be shut out simultaneously (as for instance, in the counting rooms or separate lays in the same room), without turning the keys in the individual lamps, a "switch" is inserted in the line at the junction with the central feeder coming from the generator. On a dark or cloudy day the aisles nearest the windows do not require the light as soon as those in the center of the room. The former are shut off by the switch until required, when the lamps are all turned on at once.

Where a large number of lights are distributed over several stories of a building, or where the light is required at some distance from the generator, "electric tubes" replace the ordinary feeders mentioned above. The tubes are the same as used by the Edison Illuminating Company of New York, in Edison's "First District." These tubes consist of lengths of gas pipe in which are placed two large cylindrical copper rods, separated from each other and from the tube by hard rubber insulating and impermeable washers; the intermediate space is then filled in with a fine sand and the tube is then the insulating properties of gutta percha. These tubes are laid in small trenches a foot and a half deep where it is desired to use the current. These trenches or tubes are connected directly with the dynamos or generators. These machines are of two sizes as shown in Fig. 5 and 6. Fig. 5 is known as a "Z" machine, and is capable of supplying the current sufficient to maintain 800 to 65 lamps at 16-candle power, or 125 to 100 lamps at 8-candle power. This will perhaps be more readily comprehended when it is stated that 16-candle represents the light furnished by an ordinary argand burner consuming 5 to 10 feet coal gas per hour. Fig. 6 represents the "L" machine with a capacity of 250 to 200 16-candle power, or 500 to 400 8-candle power lamps.

Fig. 7 is the "Z" machine, with a capacity of 800 16-candle power or 500 8-candle power lamps. In each of these cuts A represents the arms of the electro magnets, B the pole pieces between which the armature, D, revolves, and K the keepers. The brushes, C, collect the current generated in the armature, B, from the commutator, T. The current passes from one brush along the conductors shown on side of magnet arms to the top of the machine where it divides, part passing off by conductor, G to the feeder through the lamps back to D, and part passing about arms of magnet, joining the return current, in B, which is connected to the other brush. When the machine is first started there is no perceptible magnetism in the pole pieces

Fig. 1. Engine represented in the Edison "Steam Dynamo." The crank shaft of driving engine

(Continued on page 6.)

THE EDISON SYSTEM OF ISOLATED LIGHTING.

(Continued from Page 5.)

is lengthened out and forms the armature shaft. This machine is capable of maintaining 1200, or, in an emergency, 1500 lamps of 16-candle power each. Six of these large machines are already installed and in operation in the "First District" in New York. The current produced by all the Edison machines is perfectly harmless to the person as well as to property and can be taken by a child with perfect impunity. The reason for this is that the electromotive force (analogous in some measure to pressure in a steam system) is extremely low and is very nearly constant and independent of the number of lamps burning; it is the same on the various sizes. The quantity varies very nearly in

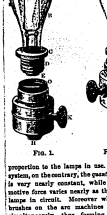

FIG. 1.

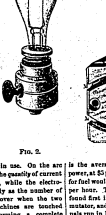

FIG. 2.

proportion to the lamps in use. On the Edison system, on the contrary, the quantity of current is very nearly constant, while the electromotive force varies nearly as the number of lamps in circuit. Moreover when the two brushes on the new machines are touched simultaneously, thus forming a complete circuit, a "counter electromotive force" is set up, which is many times the original. Thus a nervous shock is produced causing death. This "counter electromotive force" cannot be set up in the Edison system, as the circuit was already complete through the lamps; one more path was simply opened to the current. It is preferable to have the generators attached to a separate power, but it is not necessary, as the power can be applied by means of cotton belts, shaft from engine or wheel already in use. The power required to drive the various dynamos is as follows: 2, 8 horse power; 5, 20 horse power; 8, 32 horse power.

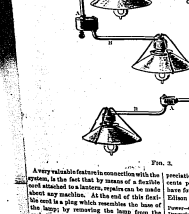

FIG. 3.

A very valuable feature in connection with the system, is the fact that by means of a flexible cord attached to a lantern, repairs can be made about any machine. At the end of this flexible cord is a plug which resembles the base of the lamp; by removing the lamp from the socket and placing the plug in which the cord is attached in its place, the current can be carried to any desired place.

The gas meters used in factories consume about one foot of cost gas per hour. One dollar's worth of 16-candle power lamps is equivalent in illuminating effect to about two such burners, and in ordinary work will replace about that number; as, however, they would give about the same illumination as at present, some manufacturers, believing "that it does not pay to run in the dark," increase the number. It has been found by experiment that standard and ample light is provided by using one 16-candle power lamp to four forty-inch boxes, or to two wide looms (say 96 to 112 inch reeds) on white goods, or the same for two gingham looms. In woolen mills, the swinging bracket mentioned above, is found especially valuable. On this class of work one of these is required for over each end of the loom, and so arranged as to swing in between the frame and the harness. This allows the weaver to keep run of the yarn on the bobbin in the shuttle box, and to "draw in" the yarn through harness, by swinging the lamp over the warp beam. On white or light colored woolens, two 8-candle power lamps per loom are sufficient. On dark colors, two 16-candle power lamps are used. The expense of lighting by the Edison system, as compared with gas, is much in favor of the former. Let us assume, for an example, a cotton mill of 10,000 spindles or about 200 40-inch looms, manufacturing sheetings and shirtings. This mill will require about 500 16-candle power lamps; the cost of installation will depend upon the length of mill, and also upon the position of the dynamo in relation to the work; but assuming an average length, the plant will cost in the neighborhood of $8000. For this purpose we shall need two "K" (250 light) dynamos, requiring in the neighborhood of 48-horse power. Assuming that, in an ordinary engine, 31 lb. of coal

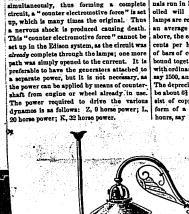

FIG. 4.

is the average hourly combustion per horse power, at $2 per short ton (2000 lb.) the expense for fuel would be the neighborhood of 3 cents per hour. The depreciation on the system is found first in the lamps, second in the commutator, and third in the brushes. The journals run in Babbitt metal, and when properly oiled will show no appreciable wear. The lamps are renewed at a cost of $1 each. With an average life of 600 hours, as mentioned above, the expense for lamps will be about 831 cents per hour. The commutator, composed of bars of copper about an inch thick, closely bound together and insulated from each other, with ordinary care will last 1500 to 2000 hours, say 1500, and can be renewed at a cost of $50. The depreciation on the two commutators will be about 63 cents per hour. The brushes consist of copper wires bound together in the form of a pillow; they will last 100 to 200 hours, say 150, and cost $8 per set. The depreciation on brushes thus amounts to 16 cents per hour. Tabulating the above, we have for the hourly expense for running 500 Edison 16-candle power lamps, as follows:

Fuel—31 lb. per hour, at $2 per ton	.03
Depreciation—Lamps	.08½
Commutator	.06
Brushes	.16

Let us now make a similar estimate on the cost of running 500 4-foot gas burners. At 22 per 1000 feet, this amounts to $1 per hour. Estimating 200 hours as the "lighting time" in factories in Massachusetts, we have a yearly cost for gas of $200, and $1,250 per hour the Edison system will cost $474, showing a saving of $726, equivalent to a little more than 2 per cent on the investment. This does not allow for depreciation, the interest on the apparatus, nor the fact that the Edison system is furnishing twice the light of the gas. Assuming $90 (cost, say, of $150) as the interest on the plant, and $400 as interest on fixtures, the former, furnishing but half the light, costs 331 per cent. more than the latter.

In ordinary manufacturing work, the above 500 lamps will replace at least 750 gas burners. On this basis the Edison system can furnish a far steadier, safer, and more healthy light, and one which does not heat or vitiate the air, at a cost of 50 per cent. original gas bills (interest on gas piping being figured at $400—at 20 per cent. on $2000). The above basis of 200 hours is the average period of illumination

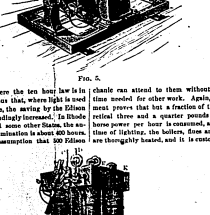

FIG. 5.

tion per year where the ten hour law is in force. It is obvious that, where light is used for a longer time, the saving by the Edison system is correspondingly increased. In Rhode Island, Maine, and some other States, the annual period of illumination is about 400 hours. Under the above assumption that the Edison

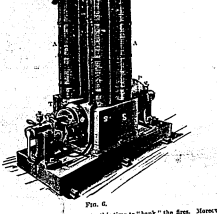

FIG. 6.

lamps of 16-candle power will replace 720 4-foot burners, in these States. We shall have a reduction equal to about 552 per cent, gas bills; or, reducing the cost to the equivalent of gas at 831 cents per 1000 feet, including 2 per cent. interest on plant. Or, to put the matter in still another form, the purchaser, from saving

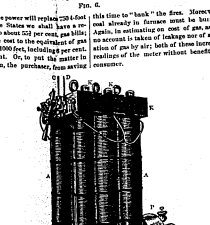

FIG. 7.

In expense of lighting his work, makes a profit greatly good investment. In these times when government bonds are 3 per cent. are considered good security.

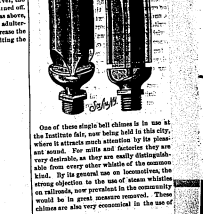
In the above calculations, it may be noticed that no allowance is made for attendance, as very little is required by the Edison system; no more, in fact, than is necessary to light the 720 burners. The general method pursued by this company is to place the dynamos in the engine room, machine shop, or other convenient place, where the engineer or master mechanic can attend to them without taking time enough for other work. Again, experiment proves that but a fraction of the theoretical three and a quarter pounds fuel per horse power per hour is consumed, as, at the time of lighting, the boilers, fires and stack are thoroughly heated, and it is customary at this time to "bank" the fires. Moreover, the coal already in furnace must be burned off. Again, in estimating on cost of gas, as above, no account is taken of leakage nor of adulteration of gas by air; both of these increase the readings of the meter without benefiting the consumer.

In mills using water as a motive power, the economy is obviously still further increased, and the cost for the above 500 lamps is reduced to the neighborhood of $1.50 per hour. Therefore, with water power the 720 4-foot burners being replaced by 500 16-candle power Edison lamps, and assuming 400 hours as the lighting time per year, the annual cost of the electric light, including interest on original outlay, will be equivalent to gas at 75 cents per 1000.

For domestic lighting the Edison system commends itself especially to the attention of householders; for, with the electrolliers and the brackets manufactured by this company, the wires are entirely concealed, and there are no noxious gases given off to vitiate the air and tarnish the metal hangings of the room, and no smoke to blacken the walls and ceilings. The lamps are now being manufactured and in use, which are connected by means of a flexible cord to the chandelier, and on which any purpose now occupied by the drop light. Meters also are used; these are virtually electrolytic cells. Each meter contains two cells, in each of which are suspended two zinc plates. One one-thousandth of the current used in the house is shunted through the first cell and one six-thousandth through the second. By the laws of electrolysis a current of a given strength will deposit a fixed amount of zinc per second. As the cells are carefully weighed before using, the accumulation of zinc on the negative pole shows the exact amount of current used in the house. The second cell is a check upon the first. As these cells might be placed in position where the sulphate of zinc solution would be frozen, an automatic arrangement is provided which will meet this difficulty. It consists of a compound spring made of brass and steel. This spring is set at 60°; the coefficient of expansion of brass being greater than that of steel (that is, the brass expands or contracts more quickly than steel), any change of temperature will tend to produce a curve in this spring and thus force the end against a contact piece, throwing into circuit an Edison lamp beneath the cells; by the slight heat produced from the lamp the mixture in cells is heated above freezing point; this heat also acts on the spring, which gradually straightens again, and when 60° is reached the contact is broken and the lamp thrown out of circuit. Thus no part necessary to the completeness of the Edison system, appears to have been overlooked by its originators, and the system now stands before the public perfect and complete in all its parts.

A NEW STEAM WHISTLE.

The "Single Bell" china whistle, a cut of which, showing the outside and the inside, is given herewith, has been before the public for about three years, during which time it has steadily grown in favor, and its sale largely increased. It is manufactured by the Crosby Steam Gage and Valve Company, at 50 and 97 Oliver street, Boston; they have exclusive control of it throughout the United States. It consists of a single bell, or cylinder, which is divided longitudinally into three compartments of unequal length, and so graduated that each gives a different tone, but so arranged that one steam valve sounds all together, and all the tones are blended into one agreeable and harmonious sound, free from the shrill, harsh noise of the common steam whistle.



One of these single bell chimes is in use at the Institute fair, now being held in this city, where it attracts much attention by its pleasing effect. For mills and factories they are very desirable, as they are easily distinguishable from every other whistle of the common kind. By its general use on locomotives, the strong objection to the use of steam whistles on railroads, now prevalent in the community at large, would be greatly removed. Those would be in great measure obviated if chimes are also very economical in the use of steam.

Remarkable Run by a Locomotive.

We note a remarkable run on the West Jersey railroad by a special passenger train, made up of a Class C anthracite locomotive, burning bituminous coal; a combination car, and two passenger cars; 114 passengers were on the train. The train ran through from Camden to Cape May, a distance as only one point, about 40 miles out, for water. The train left Camden at 2.01 P. M., and arrived at Cape May at 3.34. Records of speed were taken as follows: Westville to Cape May, 76.1 miles, in 76 minutes; Woodbury to Court House, 61.1 miles, in 60 minutes; Glassboro' to Vineland, 16.5 miles, in 14 minutes.

D. M. Smythe, the inventor of the book stitching machine made in Hartford, has gone to Europe to attend to business for the company there.

THE ELECTRIC LIGHT IN HOUSES.

FOUR years ago the famous Baron Munchausen took a trip to the moon. At the time the object of his excursion was unknown, but it is now supposed to have been taken on behalf of an electric lighting company, to discover how the soft white light, which we now obtain from a current of high tension, the light was supplied from dynamos in the comparative darkness of the moon. Whether the current could be so equalized that dynamos at any point could supply the lady at the man in the moon with an equal light, and whether the current could be distributed at all, are the Baron's chief but interesting and extensive account of life 'now does not relate. The moon named, it is to be presumed that this mission was a failure. At any rate nothing came of it, and it was reserved for Mr. Edison to evolve without a luxury excursion a method which has furnished a theme for many pens, and which has certainly proved that will soon be able to get up a little private moon, each for himself, and, by a simple system, even when the lunes are without any current, the silver rays as they come down will be a trifle dearer. Though it is to be devoutly hoped that the number of pens will not increase with the number of electric lights.

Mr. Edison's invention naturally met with much opposition, and, though the opposition has diminished considerably, there are still many who regard the electric light, in its present form, as a "delusion and a snare." The first lot of doubters, who did not believe that Mr. Edison could subdivide the current into small lights, were silenced some time ago by the actual subdivision, and soon the Edison Company proposes to illustrate to us the practicability of his system by illuminating the streets and houses in about a square mile of our city—that part bounded by Wall, Spruce, and Nassau streets, and the East River. In England the system has already been tested. Mr. Edison runs a model town there known as the Holborn Viaduct Station, and it illuminates, among other buildings, Dr. Tanner's Temple, and part of the London General Post-office. Besides the Bank Theatre in Milan, a portion of the Strasburg *Opéra*, and two steamships of the Oregon Navigation Company are lighted by Mr. Edison's system.

Yet it is certain that the inventor should meet with considerable opposition. The introduction of new forces, at first violently opposed, and now that gas is generally in use, it in turn opposed the introduction of electric light. How serious that opposition is, may be judged from the immense power at its back. It is reported that about one thousand millions of dollars are invested in gas all the world over. Of this amount about three hundred and eighty-five millions are invested in the United States, and about four hundred and five millions in England.

In selecting the down-town district for the first experiment on a large scale in this country, Mr. Edison had in view the fact that besides the large consumption of gas in this district, there is a good deal of steam motive power employed, which the Edison Electric Lighting Company proposes to supplant by electric motor power from the same current which supplies the light. A careful preliminary canvass of the district gave the following statistics: There are in the district 19,858 gas and burning between the hours of six in the evening; 1270 store-lamps, aggregating 2385-horse-power; 715 lamps and 90 chronometers, and 68 sewing-machines. Besides, the canvass elicited the interesting fact that five persons were used in the leather manufactories in the swamp. Eighty-four persons were employed in the top stories of buildings. Some of these horses are kept there from the time they are taken up until they die.

A canvass of the Madison Square district, bounded by Twenty-fourth and Eighteenth streets and the Eighth and Madison avenues, where work will soon begin, elicited facts with not less interest when contrasted with the statistics of the first district. There are in the houses 41,000 gas and kerosene buildings (hotels and theatres) burning over 600 gas jets each; 52 steam-engines, aggregating 1453-horse-power; only 8 boilers, and 14 elevators (the latter only in the hotel buildings). The buildings where the most sewing-machines are found contain the fewest gas jets.

The great saving in the current for motor power, as compared with steam, is that, as one engineer said, "while the electric motor does no run-ning, the steam-engine must run all the time." The introduction of a large number of electric motors will be required in run a large of sixteen-candle-power—the ordinary lamp. We can see a sewing-machine all day long at a cost to the consumer of five cents. There are in New York some 210,000 sewing-machines, and there is no reason why we should not supply each one with the cost of three."

The streets in the down-town district require thirteen miles of pipe. The Madison Square district embraces 180 acres, or forty-seven blocks, aggregating in length about 42,000 feet. As the pipe in this district will be laid on both sides of the streets, about 90,000 feet of pipe will be required.

The central station of the down-town district is located at Nos. 255 and 257 Pearl Street. Much work was required before the building was ready for the plant. This consists of six dynamos, and six engines to run the dynamos. Besides its incidentally four boilers, with an aggregate capacity of 1000-horse-power, boiler fittings, two large smoke-stacks, steam conveyors for coal and ashes, shafting, blowers, and the pumping and blowing apparatus. The placing of these requires vaults under the sidewalk, and a tendency iron framework resting on a strong bed of masonry and concrete. Each of the six engines has a normal capacity of 125-horse-power, and a maximum capacity of 200-horse-power, making a total maximum capacity of 1000-horse-power. A dynamo like the six used in this structure weighs thirty tons, so that the weight of the six is 180 tons. The weight of the fuel necessary to run the plant continuously for about 600,000 pounds, which is distributed on a floor to carry about 200 pounds per square foot of structure. The boilers, when under full headway, will consume 1800 pounds of coal and 4,000,000 gallons of water per annum, equivalent to a daily consumption of about the tons of coal and 11,000 gallons of water.

A full description of the dynamos belongs to electric circuits and insulation, and would fall to give an intelligent idea of the system as a whole. The dynamos, they consist in the main of powerful electro-magnets, between the poles of which a armature-coil revolves. The poles of the armature-coil are connected through the brushes with the commutator, from which the current passes by the pipe laid in the street to the various places of consumption, and similarly is given from whatever point the pipes are tapped into the circuit. The strength of the current can be regulated according to the amount of work required of it at any moment, so that there will be no waste of power or material. A regulator, namely, by varying the resistance of the circuit of the dynamo-field magnets, weakens or strengthens the current induced in the armature. An electro-motive-force indicator shows instantly any variation of the current produced by increasing or re-arranging any of the number of lights in the circuits. A supplementary instrument shows in the circuit of a number of "plus lights" in the regulating room.

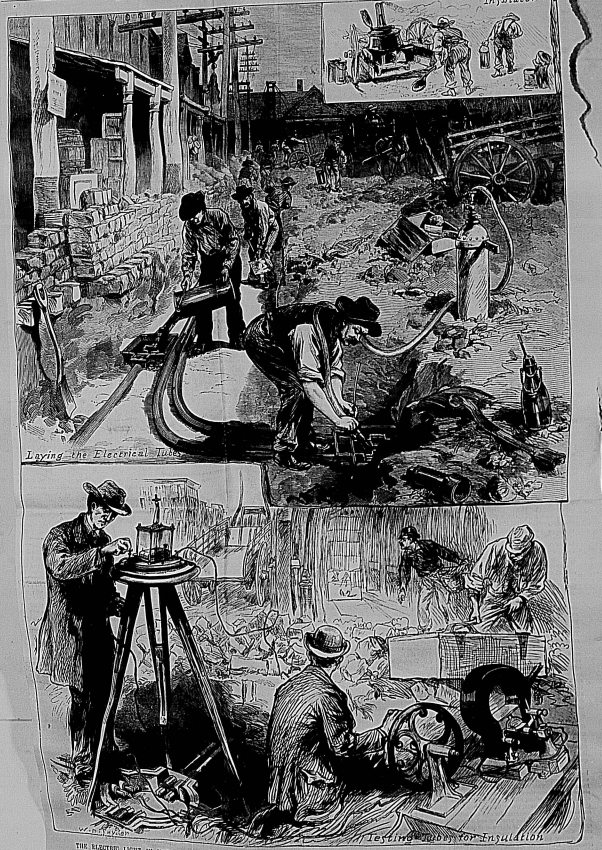
The laying of the pipes and boilers is a curious and interesting and popular feature of the work. The water remembers how much current was used exactly in October last by the queer-looking pipes and burns that were being piled up on the sidewalks of Gold, Spruce, and William streets.

Walking down Spruce Street one day he saw a number of people gathered at the corner of Spruce and William streets looking into a hole. In the hole a few feet below the surface was an iron pipe, which was covered with rough boards. But there was no one to explain the noises *Nitre* either of the hole or of the pipe. Soon workmen came along and began filling up the hole, but they had no information to give. Looking into Spruce Street, though, the writer saw that digging was going on in Gold Street. As he neared the spot he saw brace similar to that in the hole on William Street piled up on the sidewalk. The roadway on either side was dug up a few feet below the surface. A man was shipping about in the ditch with a tape measure, and several others were measuring small iron pipes, from which the thick pieces of metal projected. When an iron pipe was measured, a mark was made on it, and it was then lifted into the ditch. The writer was told by a man who was helping to lower the measuring pipes from which wires were to be led into the houses and business places of a portion of the district bounded by Nassau, Wall, and Spruce streets and the East River; and that Mr. Dynne, one of the engineers of the company, could explain the process.

According to Mr. Dynne, the pipes are ordinary iron pipes which insure thick copper wires and which are laid in the streets. The pipes lying on the sidewalk—separated from the curb by an iron railing—are intended for the houses, not differing much in size, are used. They are about ten inches in diameter, and are of cast iron. They are respectively junction boxes, connecting boxes, and distributing boxes. The junction box, of which the circular of the coupling and service boxes, is a combination of these in the coupling and service boxes. The junction box is the coupling box, to which connection between two pipes is made. The pipes rest on sections cut into the sides of the box, the pieces of metal projecting from either side being connected by clamps. The box is then filled up with a rubber insulating fluid, which cools into a solid. Then the lid of the box is closed. The combination coupling and service box is the same as the last, except that the coupling has a third, through which the wires are "served" to the houses.

The safety box is an ingenious contrivance to prevent danger from the heat caused by accidental crossing of the wires. The principle on which it works is as follows: Should wires cross by accident, the damage caused by the crossing heat would be considerable. In the safety box the fuses of copper wire are interrupted by lead. At most instantaneously with the crossing of wires the heat rises along to the lead and melts it. The result is to break the danger zone at once. These boxes are on the corner of every street, and are so arranged that the wires can be traced to any of those whether in the house or along the block are in good condition. Through the junction boxes the wires pass from the street mains in iron wire and enamelled cloth. Each wire is then led to the meter, which registers, for he looked on her as a superior being? Perhaps she was the current consumed. The meters are simply clocks, and her Nademan-like head was full of the mysteries and her father thought highly of her, and consisted at his visits, and as they were often together in a friendly way, but she has to be gone to make downright love to her, she told him plainly she could go no further in friendship than "and indeed," said she, "I would never leave my father for any young man."

Joseph Pinder knew that this declaration has just "Joseph Pinder knew that this declaration has just "Joseph Pinder knew that this declaration has just the friendly sensibilities and times two other men were in love with her, and that she was fond of them all, fight at being merely friendly, and she cool and friendly, and that she was fond of them all, fight at being merely friendly, and she cool and friendly, and that she was fond of them all, fight at being merely friendly, and she cool and friendly



THE ELECTRIC LIGHT IN HOUSES.—LAYING THE TUBES FOR WIRES IN THE STREETS OF NEW YORK.—DRAWN BY W. P. BEYCOK.—[SEE PAGE 394.]

July 25, 83. Phila Pa

THE OLD RELIABLE FALL RIVER LINE.

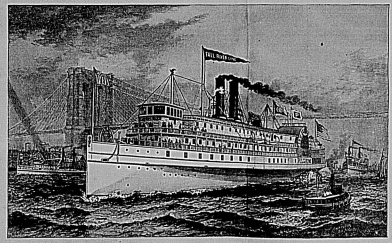
Since steam navigation began, the Thames or "North" River and Long Island Sound have each had their night lines, each progressing, in construction and fitting, through successive steps of size and magnificence. The Sound, however, is the greater water-way, open all the year, lying between the more important points, and serving for the larger fleet; the vessels there are the largest, strongest, and costliest, and the best of them have no equal in the world. Of the several lines, at times four but now three,—the Fall River has always been the leading one, and is now more than ever so. Its supremacy was first assured by its geographical position. Having three tenders for freight and two for passengers, it has always offered to the travelling public the unequalled advantage of long water-route and short rail, so that a whole night's rest is secured, and not merely half a one. An admirable rail service, offering choice of several morning trains Eastward from the boat, has supplemented this. The management has also been exceptionally progressive and pushing, and the world-wide popularity of the "Fall River Line" has been partly made by (and has partly made) the construction of the newest, largest, and incomparably superior boats afloat, vessels which without hyperbole may be called floating palaces.

From the time of the old and the wonderful *Bay State*, *Empire State* and *Metropolis*, the advance to the boats of the Line to-day is marvellous in all respects. The *Old Colony* and *Newport*, still running as the Newport boats in summer and the Fall River ones in winter, may still be called new and can hardly be excelled by the best vessels on other lines. Then came the mammoth *Priscilla* and *Providence*, originally built for the successful Bristol line, and they have been the kings of the Sound for some ten years. In features of construction which are apparent to the casual glance, these superb vessels are extremely unlike any of their predecessors; their holders are below deck, instead of "on the guards" outside; the wheels, wheelhouses and towns are less prominent, and they have more the appearance of sea-going vessels.

The careless outsider might suppose that the Fall River Line had vessels enough, and had built the *Pilgrim* (see the fine illustration accompanying this article) as a sort of present to the travelling public, or just to show what can be done by a corporation having the money, experience, and enterprise. This Line has always been the Consul of the Sound in respect to safety and humanity (even a misfortune, purchased by good management); it has combined with the White Star regularity of trips the Golon reputation for speed, and in bringing out the *Pilgrim* it discourages competition, or (if it be more American to say so) invites and challenges competition to come on.

The old New England flavor and history come to the front in the name of *Pilgrim*, and it has perhaps been forgotten by most of their thousands of passengers that the *Bristol* and *Providence* (belonging to the line by adoption, not birth) were originally intended to have a New England air, in the names of *Puritan* and *Plymouth*. The Fall River Line set out to build a steamship, and it is a simple truism to say that *they have done it*.

Externally the *Pilgrim* looks like her two sisters, except in having a simpler and subtler appearance by having the usual "big-chimney" and by having her two 4 twin-stacks near together and in line with the keel. But she is distinctive in being fire-proof and collision-proof. Of iron—double-skinned, being a ship within a ship, and as strong as if intended for an iron-clad for war purposes—for over a hundred water-tight compartments, and would not sink if her bottom were broken in. Her engines and boilers are iron-encased; the pantry has iron ceiling and walls, and (last floor) the kitchen is similarly protected, and there is no fire elsewhere on the boat; abundant hose and pumps complete the precautions in this respect. The twelve steel boilers are capable of developing 5,000 horse-power. Steam moves the huge rudder, and the steersman has only to start the engine which does his formerly hard work for him. Electricity does the lighting.



The light is worthy of a separate paragraph, and does of a separate article. The system is of course Edison's. There are 321 lamps and candles the same lamps in some other steamboats the power is not supplied parsimoniously, and the lamps give standard light. Two engines, supplied by a 150 horse boiler, run the three dynamos, and these can be also connected to the regular "donkey" engines, if need be. The Edison system is perfection itself, as regards safety from fire and personal injury; fire is impossible, the wires may be handled with impunity, the lamps will not burn the hand, and breaking their globes instantly puts out the light. There are six miles of wires for the light-system, and nearly a ton of candles, with their intolerable heat and disagreeableness, would be required for the same work; the Edison lamp gives out the least heat possible for a light, and if it *nothing but heat, having absolutely no effect upon the air except to warm it.* The grand saloon, decks, and passages are illuminated by beautiful electoliers of from two to thirty-six lights, and in each room the occupant has simply to touch a key in order to flood his room with light; there being, of course, an electric "call" or annunciator close by for summoning a servant. The light-system is divided into separate sections, so that no accident to the engines or boat can put the boat in darkness. Nervous passengers need not dread the imaginary burglar at the window, or the actual disorderly person; there is too much light for disorder, and a touch of the finger, in any emergency, real or fancied, makes everything as bright as noon. Could anything more perfect or desirable be imagined?

It is rather discouraging to try to describe the *Pilgrim's* decorations. They resemble those of her sister boats in departing widely from the old-time white paint with gilt gingerbread, which gives place to marquetrie in natural woods, real elegance in upholstery and carving, and tasteful but indescribable combinations of "picked out" and neutralized and contrasted color. There are carpets by the mile, four acres by the square acre; beyond this, one must fall into a bewilderment of panels, cornices, bronzes, etc., with hints of Vaniyke brown, salmon, rose, gold, maurelive blue, pearl, stone-gray, seagreen, and every other tone which taste can devise and money secure. From eleven saloons—including, ingleni, lavatory, dining-room, hall, stateroom, saloon, mast, passage, barber, butcher, fire-staff, dog, commander and deck-hand, the *Pilgrim* was meant to be the highest, attainable perfection, adapted in each part to its purpose, and the verdict of seeing has already been pronounced. She measures 376 feet in length, weighs some 3,500 tons, can talk 1,200 persons away to sleep, is the largest inland steam vessel in the world, and cost (if any passenger cares to know) a round million.

The Fall River Line has thus the greatest number of boats, and by comparably the finest; the largest rail portion, with the largest number of sleeping cars; the only attraction of water-travel; the only direct Brooklyn and Jersey City connecting by Annex boat. It also has unequalled freight capacity with four exclusive freight steamers running, the largest of some 2,500 tons. To its aim nor secrets are old: line offers a most varied selection of boats to all places of interest, and will make for him other combinations not expressly stated. If there were anybody who ever travels or will travel, and had not already heard of it, body who ever travels or will travel, and had not already heard of it, he might be urged to inspect the *Pilgrim* and try the Fall River Line he might be urged to inspect the *Pilgrim* and try the Fall River Line —he could not condition like Touchstone, "when I was at home I was in a better place." If any regular traveler did not know of Mr. Oscar L. Conner, the boat-in-himself Passenger Agent (O. P. A.) for about 10 New York, he might be expressly mentioned. To those who possess his acquaintance it isn't necessary, for he is himself a sort of dividend to the possession of the *Pilgrim*.

switch-stand shown by this company has an effective self-locking lever handle; the operation of locking the rail after the throw is made by simply dropping the handle, it having a forked end which drops upon a projecting lug. A rail brace for frogs and curves is another notable exhibit. This is made by simply twisting a piece of short flat iron ⅜ inches thick, so that the lower end which remains flat can be drilled to receive the bolts holding it to the crossties. The upper end, owing to the twist, has a vertical position which is out to fit under the shoulder of the rail. Such a brace is of course more serviceable and less liable to break than the ordinary cast-iron ones.

Engineering Instruments.

OAKMAN & SONS.

Messrs. W. Gaskan & Sons, of New York, show their improved levels and transits for the use of civil and mining engineers. The level made by them has a long center bearing in the telescope so that the object end can be moved for use, smoothly and accurately. This bearing is continuous and made of the best gun-metal. Some new and important features have been introduced in the manner of adjusting the instrument which makes this operation easily and expeditiously performed. Their transits are also improved upon in many respects, noticeably so in having gun-metal bearings, ground glass shades for the verniers and shifting centers for plumb and instrument without disturbing the tripod.

This firm have in addition a mining transit with a solar attachment for reconnoissance or underground surveying, possessing many features which renders it desirable for the mining engineer who has both underground and surface work to perform.

YOUNG & SONS.

Messrs. Young & Sons, of Philadelphia, the well-known makers of instruments of precision for civil and mining engineers, have a well selected display of transits and levels for use on railways and in mines; also the new Davidson level; solar transits and compasses, level rods of different kinds, also transit rods, chains of different lengths, tapes, pins, note-books, etc. They have on exhibition a transit made by themselves in 1832. It has an inside vernier, universal bubble, ball and socket-joint, otherwise it appears like the ordinary railway transit of to-day, only smaller and lighter. It has been in constant use, and was loaned to the firm by a Pennsylvania surveyor for the Exposition.

L. MANASSE.

Mr. L. Manassee, of Chicago, optician, manufacturer and importer of optical and mathematical instruments, makes a large and attractive exhibit. He has the Gurley level and transit, level and transit rods, tape lines of all kinds, Swiss and German drawing instruments, surveyors' and mining compasses, colors, brushes and drawing paper for the engineer, draughtsman and artist. He has also the "Positive" T square and section liner, it is positive in all its motions, has measurements in fractional and decimal parts of an inch, working with accuracy, and by it lines can be drawn at any angle on any part of a draughting board.

KEUFFEL & ESSER.

Messrs. Keuffel & Esser, of New York, have a large and varied exhibit of engineers' and draughtsmen's instruments, including transits and levels, with their accompanying rods for the use of civil, mining and hydraulic engineers; machinists' rules—engine-divided—U. S. standard or metric measurements; draughting tables and instruments of all kinds; also planimeters, protractors, stereoscopes, mercurial and mining barometers. Their latest novelty is the "unique" T square, with patent swivel, locks instantaneously at any angle, and has a single movable head.

STRASSBURGER & CO.

Messrs. Strassburger & Co., of Chicago, have an exhibit of instruments of their manufacture, consisting of a level, transit and the accompanying rods, tape-lines, chains, reading glasses, etc. The levels and transits made by them have the latest improvements, and are of the different sizes in general use. The exhibit reflects great credit upon this western house.

BUFF & BERGER.

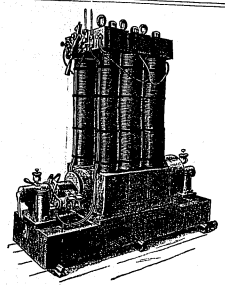
Messrs. Buff & Berger, of Boston, have an excellent display of engineering instruments of all kinds, including theodolites, astronomical instruments, mercurial and mining barometers, field glasses and telescopes.

THE EDISON DYNAMOS AND METER.

The large illustration shows the Edison Central Station Dynamo of 1200 lamp capacity. It may be observed that in this machine the field magnets are placed in a horizontal position for the purpose of securing connections and economy of space; the engine and dynamo rest upon the same bed plate. This machine was designed especially for town use or village lighting, where overhead conductors are used and streets as well as buildings are to be lighted, thus being termed the "Village Plant System."

The engine shown as connecting with the large dynamo, is a Porter-Allen high speed engine, especially designed for the purpose of driving dynamos, being termed the "Standard Pattern," and is manufactured solely by the Southwark Foundry and Machine Company, of Philadelphia. They are generally run at a speed of 250 revolutions per minute, developing 125-horse power when driving 1200 lights.

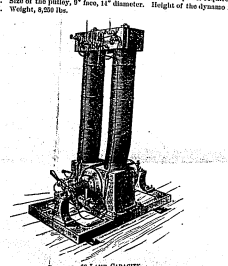
An engine of this class is driving the Edison dynamos at the Chicago Railway Exposition. It is 100-horse power and drives 350 Edison incandescent, and 60 Thompson-Houston arc lights. The cylinder is 11½" dia-



DYNAMO—550 LAMPS CAPACITY.

meter and the piston stroke 20". This engine at 230 revolutions per minute develops 100-horse power with 85 lbs. initial pressure in the cylinder.

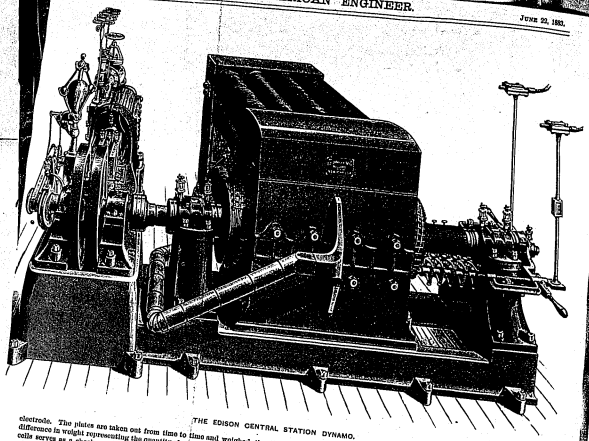
The dynamo shown as having six vertical magnets has a total lamp capacity (16 candle) of 550 lamps. The revolutions of the armature per minute to produce this light should be 900, and the horse-power required is 12. Size of the pulley, 9" face, 14" diameter. Height of the dynamo is 6' 6". Weight, 8,250 lbs.



DYNAMO—20-LAMP CAPACITY.

The dynamo shown with two vertical magnets has a total lamp capacity (16 candle) of 60 lamps. The revolutions of the armature are 1200 per minute, and the horse-power required is 3. The size of the pulley is 5" face and 10" diameter. Its height is 6' and weighs 300 lbs. The Western Edison Light Company, of Chicago, also manufacture dynamos having lamp capacity of 100, 165, 250 and 300 lamps respectively. In all these smaller machines the magnets are vertical.

The meter used in connection with the larger dynamos, when several persons are supplied with light from the same machine, operates as follows: As the electric current passes through the meter a portion is diverted through the corrugated shunts and the electro-lyte cells. These cells being partly filled with a solution of sulphate of zinc, to which are inserted the electrodes of zinc, chemical action resulting from the passage of the current causes a transfer of zinc from the positive to the negative



THE EDISON CENTRAL STATION DYNAMO.

electrode. The plates are taken out from time to time and weighed, the difference in weight representing the quantity of current used. One of the cells serves as a check upon the other and all the meters, whose used in a large system, have a check in the large meter at the central station which

EDISON METER.

automatically records all current produced by the dynamos. This ingenious device is said to operate within 1 per cent. of accuracy, and as there can be no leakage of current the consumer pays only for the actual light used.

PROCEEDINGS OF SOCIETIES.

ENGINEERS' CLUB OF PHILADELPHIA.—A regular meeting of this society was held June 2, 1883. Mr. Washington Jones in the chair; 18 members and one visitor present. Mr. Carl Hering read a short article on electrical units and formulæ, giving a list of the units and the relations existing between them; showing how these relations were known. blood into formulæ containing any two or more of the units, for convenience of calcula-

tions. The units are: *ampère*, the unit of current strength; the *volt*, the unit of electromotive force, the *ohm*, the unit of resistance; the *coulomb*, the unit of quantity; the *ampère hr* or *volt*, the unit of capacity; the *volt-coulomb* or *joule*, the unit of energy; and the *volt-ampère* or *watt*, the unit of power. The relations are that an ampère is a volt divided by an ohm. An ampère is a coulomb per second. A farad is a coulomb divided by a volt. A volt-coulomb is a volt multiplied by a coulomb. A volt-ampère is a volt multiplied by an ampère. As these relations contain no coefficient other than unity, they express the relations between any quantities measured in terms of those units, as well as the units themselves. Professor L. H. Haupt exhibited a drawing of the Phœnixville Bridge which was built by Mr. Morgan Robinson, C. E. (formerly Member of the Club), in 1866, for the Philadelphia and Reading Railroad, over the Schuylkill. It is a two lattice and one special skeleton 72 feet chord spans and 184 feet of iron masonry. There are four regular lattices of 175 feet each, and whole length of the bridge 1,000 feet. Yearly inspection of this bridge is said to be entirely filling. It is believed to be one of the lightest and oldest lattices of its kind in this country, having cost but $28,000.

The Secretary exhibited a sample of Japanese paper which he had obtained through Mr. J. L. L. Waddell. Many years ago papers were of excellent quality and could probably be used with great advantage in engineering practice. The method of manufacture is a large secret to some extent, as there is no patent law in Japan. Just the paper is made of new material instead of old rags, as in America. The best qualities are made of silk; the others probably of bark fibre. The specimens exhibited are about 20" X 24½", and would cost but a few cents each to import. The Secretary presented the following communication, which he had received from Mr. F. Hecht, member of the club: "I enclose a few blanks being 'Application for Admission' and 'General Regulations' regarding an International Exhibition which is to take place next winter, at Nice, France. Some of the readers may desire to avail themselves of this opportunity. Mr. Cassaboom, Secretary of the Commercial Exhibition, will be President of the Committee. By applying directly to him or through me the latter may receive all information desired. I am a member of the Committee. Please return blanks with application." Mr. Hecht requested for any further particulars, any one can obtain any information he desires.

LITERARY NOTICES.

THE MATERIALS OF ENGINEERING, PART II., IRON AND STEEL. By Bourne H. Woodbridge, A. M., C. E. Size, 7½×5. Pp. 104. New York: John Wiley & Sons, 15 Astor Place. $0.50 paper cover, $1.00 cloth.

In this little volume the author has given clear concise descriptions of the processes of the Manufacture of Iron, Steel, and Malleable Cast Iron. 2. Manufacture of Cast Iron. 3. Manufacture of Wrought Iron. 4. The Ores of Iron. 5. Reduction of Ores. 6. Manufacture of Steel. 7. Manufacture of Steel. 8. Chemical and Physical Properties of Iron and Steel. 9. Strength of Iron and Steel. 10. Effect of Temperature and Time on Resistance. 11. Flow of Metals. 12. Fatigue; Weshler's Law; Launhardt's Formula. ELECTRIC LIGHTING.

The Practical Working in This Important Branch of the Electrical World.

Illustrations of the United States Electric Lighting Company's Plant.

For the purpose of presenting a popular view of the subject of electric lighting we give several illustrations of the United States Electric Lighting Company's plant, which has been in operation for over a year at work in the Railway Exchange Building, at Chicago, run by a Westinghouse engine and lighting a considerable part of the building. The light is also in use by a large number of prominent establishments all over the country.

The purpose of this article is to present a brief description of the Weston dynamo electric machines, supplied by the United States Illuminating Company. The last light is a mile and a half from the battery. There are two Watts-Campbell Corliss engines, of fifty horsepower each, stationed in Prospect park to supply the light. The effect of the night was magnificent. The softness and brilliancy was altogether different from what one has been accustomed to in the perfect electric lights furnished for local purposes. It threw out the shadows sharply and strong, presenting almost as remarkable pictures of all below and around—pallid, but clear and strong. As persons passed beneath the rays their sharp shadows rotated around them as they moved. The outline of the bridge was thrown in sharp relief beneath, its reflection in the waters almost completing with it a perfect circle. From the towers the view was unspeakably grand. The two great cities lay beneath in irregular outline, with patches of deep shadows here and there and spots of bright glare between. Each circuit is worked by two twenty-light Weston dynamos, coupled in tension, and driven by an independent Corliss engine, of the Watts-Campbell type. Considerable margin has been provided both in dynamos and steam plant, in view of a probable increase in the number of lights.

COMBINED AUTOMATIC REGULATOR AND CIRCUIT INDICATOR.

As the structure of the bridge is mainly of iron, unusual difficulties have been encountered in regard to insulation; but the approach to the City of Chirches. From the Brooklyn side each light looked like a glorious beacon inviting the citizens of New York to a haven of repose.

There are in all seventy arc lamps in two circuits of thirty-five lamps each. Of these fourteen, are placed in the main span, fifty on the approaches, and the remainder at the stations at each end, and in the engine house. The two circuits are entirely independent of each other, and are so arranged as to take in alternate lamps entirely around the bridge. As the bridge, with its approaches, is more than two miles in length, the two circuits comprise more than a mile in length, the two circuit conductors more than four miles of wire.

There are in all seventy arc lamps of the Weston double carbon type, arranged

witness the grand spectacle. On the two towers, on both sides of the river, men, women and children came out to gaze upon the dazzling scene. The lights that usually glimmer and blaze in the two cities paled their ineffectual fires before the wonder. From the New York entrance to the bridge the scene was particularly striking. Every light looked like a watch-fire seatinel guarding the approach to the City of Churches.

There are in all seventy arc lamps of the Weston double carbon type, arranged in two circuits of thirty-five lamps each. Of these fourteen, are placed in the main span, fifty on the approaches, and the remainder at the stations at each end, and in the engine house. The two circuits are entirely independent of each other, and are so arranged as to take in alternate lamps entirely around the bridge. As the bridge, with its approaches, is more than two miles in length, the two circuits comprise more than a mile in length, the two circuit conductors more than four miles of wire. Each circuit is worked by two twenty-light Weston dynamos, coupled in tension, and driven by an independent Corliss engine, of the Watts-Campbell type. Considerable margin has been provided both in dynamos and steam plant, in view of a probable increase in the number of lights.

As the structure of the bridge is mainly of iron, unusual difficulties have been encountered in regard to insulation; but these have been surmounted in a very satisfactory manner, and the arrangement and position of the circuits is equitably to be commended. The wire used for the mains is insulated by a thick coating of kerite, wound with a kerite tape, and the whole enclosed in a heavy braid of braided cotton.

As the alternate lamps are entirely independent of each other, in regard both to circuits, and to dynamos and engines, the chance of any accidental stoppage of all the lights at once is very much less. In order to provide every possible safeguard, arrangements have been made for connecting the bridge circuits with the lighting stations of the United States Illuminating Co. in New York whenever desired. This company also light a very large portion of New York City.

The illustrations in actual operation it will be seen that electric lighting has passed the experiment stage, and is already a thing numbered with the great steps of progress of this age. The system adopted by the United States Electric Lighting Company consists of the Weston arc system and the incandescent system comprising the Weston dynamo and the maxim incandescent lamp.

The Weston has been found by tests to give a higher result in electrical energy than that of other machines, and added to tests recently made at the Paris Exposition the company state that "very important improvements have been made in the Weston machine, by which a considerably higher efficiency has been obtained. Recent tests of our machine of the present type have shown a conversion of from ninety-eight to ninety-nine per cent of the power applied in driving the machine into electrical energy, and an actual or working efficiency of more than ninety per cent. That is, more than ninety per cent of the power used in driving the machine is available as electrical energy in the working circuit for producing light or power.

This extremely high efficiency is due to scientific correctness of mechanical and electrical design, great care in the study of details, and thorough workmanship and excellence of materials employed in construction."

The large cut herewith gives a general view of the machine and from which it will be seen that the great strength of the frame and rigidity of the bearings, supplemented by extremely accurate mechanical work, admit of running the armature with very slight clearance between its periphery and the pole pieces of the field, a condition essentially for high electrical efficiency.

The sectional armature is one of the most striking distinctive features of the Weston dynamo machine. By its use the formation of induced currents in the core is entirely obviated, and the armature is made to act as a centrifugal blower to maintain a rapid circulation of air and prevent injurious heating.

The field coils are placed in a branch or derived circuit of high resistance, instead of in the main circuit, as is usual in other machines.

Great advantages are secured by this arrangement; less power is required for sustaining the field; the current generated is more steady and the machine more uniform in its operation; it is impossible to injure the armature by short circuiting, and the regulation of the machine is more simple, perfect, and economical than is possible with any other construction.

The machine used in the arc and incandescent systems are of the same general type, the principal difference between them consisting in the winding of the armature and field coils, which is varied to produce the different qualities of current required.

The current generated by these machines is absolutely continuous, and free from the rapid vibrations or pulsations which render the current used in many other systems so dangerous to life.

In both systems the regulation of the machine is entirely automatic. Lights may be turned on or off at will, and a corresponding change is at once made in the current generated, and in the amount of power required for driving the dynamo.

In the incandescent system no special regulating mechanism is used. The dynamo itself is so constructed that the strength of the current generated is always directly proportioned to the number of lights in circuit. The result is not produced by any readjustment of parts, but necessarily follows from the law of operation of the machine itself. Turning lights on or off of itself instantly increases or diminishes the current correspondingly, and this operates with such quickness and precision that with a hundred lights, for example, in circuit, ninety-nine may be turned out instantly without sensibly affecting the brilliancy of the remaining light, and without any change in the adjustment of the machine.

INCANDESCENT LAMP HOLDER AND SWITCH.

The importance of this remarkable capacity of the Weston machine can hardly be over-estimated. In the incandescent system the number of lights in use is often subject to sudden fluctuations which would, without perfect automatic regulation, not only produce unpleasant variations in illuminating power, but endanger or destroy the lamps.

In the arc system, owing to the different arrangement of the lamps in the circuit, a separate regulator, shown in illustration, is used with the machine. This consists of a rheostat placed in the circuit of the field coils, and simple mechanism for automatically adjusting its resistance so as to vary the strength of the field magnets, in accordance with the number of lamps in circuit.

This regulator is extremely simple in construction and efficient in operation, and entirely obviates the waste of power and disturbance of the proper operation of the machine, which are incident to all other methods of regulation hitherto applied to arc systems.

In both systems any number of lamps, up to the full complement, may be run by the machine, and the expenditure of power is very nearly proportional to the number of lamps used. In the character

SAFETY. ECO

tal quality of the light produced, the incandescent system is the most perfect means of artificial illumination yet discovered. Although it is, for lighting large spaces, greatly inferior to the arc light in economy, it is admirably adapted for general interior illumination in places where arcs are light would not be suitable, and for a great variety of uses is unquestionably cheaper than gas or any other system of lighting.

The Weston machines for running incandescent lights are especially well fitted for use as motors; and, in addition to these, they are building a number of special sizes of motors for furnishing small amounts of power, which may be run on the same circuits with incandescent lamps when desirable.

The Weston system of regulating motors, which the company will shortly be prepared to introduce, they claim to be the only one yet devised by which different motors in the same circuit can be governed independently without waste of power.

The United States Electric Lighting Company furnishes a large portion of the illumination for the Chicago National Railway Exposition. It has put in over twenty thousand feet of insulated wire, and two hundred electric lamps, each light requiring seven tenths of one horse-power. At the northeast corner of the Main Exposition Building, within a space measuring, possibly, 45x35 feet, surrounded by an iron railing, stands a neat booth or office, handsomely painted and finished. Adjacent to the office, and to the left as the visitor approaches, is a magnificent one hundred horse power Buckeye stationary engine. This, in conjunction with the Washingtonian engine at the southern end of the building and a large Corliss in the west side, supplies the requisite power for running the dynamos. Of these wonderful electric machines, capable of reversion at a moment's notice into powerful motors, there are seven in close proximity to the office and numerous others scattered about the building. To the left of the large engine is a four horse power Weston electric motor, deriving its motive power through an ordinary-looking cotton-covered copper wire connected with a large dynamo at the other side of the exhibit. From this motor runs a belt which operates a pump, capable of raising two hundred gallons of water every minute. The water pumped is elevated one foot through a 4½-inch pipe to a tank, whence it is discharged a miniature waterfall surrounded by profuse shrubbery and imitation walls of rock. Behind the steadily falling sheet of water are arranged a number of electric lights in brightly-colored globes. The effect is startling every time of the rainbow appearing, disappearing, and blending in rapid succession.

Hanging in irregular profusion around the cluster of electric machinery are brilliantly-glowing lamps of both the Maxim incandescent and Weston arc pattern. At regular intervals along the entire eastern side of the building and down the center, reaching to the extreme southern end of the annex, are strung the United States Lighting Company's lamps. The press-room, ball leading to it, large restaurant, commissioners' offices, etc., are also supplied with lamps from the same source, either in single lights or in shape of pendant chandeliers.

The seven Weston dynamo-electric machines on exhibition comprise dynamos ranging from one forty-light arc to a five-hundred-light arc. The largest incandescent dynamo furnishes two hundred lights and the smallest fifteen lights. These are entirely separate from the 125 arc and 100 incandescent lights operated from engines in other parts of the building.

The electric railway running entirely around the gallery of the building, operated on principles entirely original as regards the application of electricity as a railway motive power, is also run by an electric current furnished directly through two Weston electric motors.

The entire exhibit of the United States Lighting Company at the Exposition is under the management of Mr. Alex. P. Wright, an electrician of long experience in both the United States and Canada. While the company has been located at New York for some years, and had its main offices at Nos. 80 and 81 Liberty street, New York, it has recently opened an office in Chicago, in charge of Mr. C. C. Warren, at 185 Dearborn street. Mr. Warren is a practical man, thoroughly conversant with the construction and operation of the electric lighting business, and has succeeded in placing a very large number of these circuits of arc lights in the West.

ELECTRIC LIGHTING COMPANIES.

A great number of companies have lately been formed for the purpose of practically applying recent discoveries in electrical science. The eagerness with which the shares of those undertakings are being absorbed by the public, is very remarkable, considering that absence of speculation in other departments. Something must, no doubt, be allowed for the novelty of the schemes in question, something, too, for the beauty and magnificence of the results obtained from the use of electricity as a lighting agent. It is certain that the astonishing effects produced by this mysterious natural force were incapable of dazzling the intelligence as well as the eyes of those before whom notice it has been placed. From one point of view, the readiness of the public to subscribe for shares in electric companies is not to be regretted. The new companies will have a fair chance of showing what they can do to redeem their promises, and in the long run the best system or systems—for it is quite conceivable that there may be several practically equal excellence—will become established in public favour. But before that happy consummation arrives there will, in fact, be a period of some trouble and anxiety to be gone through even by the shareholders in the companies which are destined to come safely out of the struggle for existence which is evidently before them. Without questioning the wisdom of those who hold that electric energy will eventually be largely used for illuminating purposes, it may be suggested to those who are thinking of investing in the shares of new electric companies, several of which were until within the last day or two apparently nearly ready to start, that they should clearly recognise that they are putting their money into a speculation, and not into an established investment. The difference between the two is not always appreciated by the class of persons who rush at the issue of any new undertaking. In the present state of development of electric lighting, the companies which have been formed to supply electricity for this end, and other purposes are very much in the position of mining speculations. That they may be successful may be fully conceded, but that they will all be successful is far from probable, and the difficulty of determining which are most likely to be so suggests the necessity of a cautious selection of their company by those who are tempted by promises of high profits.

It seems clear that no fewer field than electric companies for the display of the astuteness of the promoter has been discovered for some time. The rapid increase of the system of electric lighting is a matter on which only experts and those who are qualified experts, in this branch of electrical science are by no means conscious. The progress of invention has been so rapid that the supply of adequately-instructed electricians is not at present equal to the demand for them. Another reason why people with money to invest, which they would feel the less of, should think twice before applying for shares in an electric company, is the doubtful value of many of the patents on which reliance is placed by writers of prospectuses, not that the inventions they are supposed to protect are of no value, but that they have already been patented by some one or other. Even as regards the most recent inventions disputes arise as to priority, which will probably soon furnish a fine crop of litigation. The differences between the four best known incandescent lights are almost nil, to the uninstructed eye, variations in the form of the carbon filament being to all appearance the principal point in which they differ the one from the other. And each of the companies which work them has already obtained one or more of its rivals with injunctions to restrain infringement of patents. Finally, what is more likely than that some new system may be invented which is as good as, or possibly superior to, those on which the companies now starting into life depend? Electric Lighting and Power stocks may very properly be held by those who have money which they can afford to lose without inconvenience. If they choose their company or companies well they may not lose, but, on the contrary, may gain profits, which ought to be proportionate to the risk run. But those who cannot afford to go without a return for their money, and whose circumstances may compel them to realise at an unfavourable moment, might do very wisely indeed, not only of the financial bona fides of the company, but also of the practical efficiency of the electric system it is to work, before they buy its shares. "Above all" let them beware of thinking that, because there was lately an enormous rise in "Electric Lights," the shares they think of applying for will rise too. In the first place, every fresh issue necessarily reduces in some degree the market value of all securities of the same class as itself. When new issues are numerous and frequent, the effect on the value of the mass of existing capital is sure to be perceptible after a time. In the next place, there are strong reasons for thinking that the rise in question was not wholly due to the merits of the undertakings concerned, but partly to market manipulation; that it was, in fact, due to a "corner." The heavy fall that has occurred this week may perhaps convince the sceptical that the market was a dangerous one for a speculator who was not "in the swim" to meddle with. Any market, however large, may be "cornered," as was seen in Liverpool last year, if a sufficient number of speculators have sold "for the fall." The electric light market is a small market—a ridiculously small market considering the noise it has made—and is consequently easily manipulated by a few powerful operators, especially with the public to help them by taking up the shares freely.

MAKING ELECTRICITY FOR THE BROOKLYN BRIDGE.—SEE 7TH PAGE.

LIGHTING THE BRIDGE.

WHY THE CONTRACT WAS AWARDED TO THE UNITED STATES ILLUMINATING COMPANY.

Dissatisfactory of its System.—Report of the Special Committee to the Bridge Trustees.

Since illumination by electricity first began to be used there has been no more important undertaken by any electric light company in the world than that of lighting up the Brooklyn Bridge. The excellence and skillfulness so far displayed by the Bridge trustees have been exemplified by electricians, involving in a number of intelligent illumination, simultaneous and reliability, and, above all, safety. A special committee was appointed by the Bridge trustees to consult and determine what system of electric light lighting was to be adopted, and after the most exhaustive examination of systems of electric illumination, the contract was finally awarded to the United States Illuminating Company, which, as will occur easy to the United States Electric Lighting Company and then the Weston, Maxim and Farmer patents. The Weston arc light is the one used on the Bridge, and a word by way of point out here the advantages it possesses over other systems now in use:

ADVANTAGES OF THE ARC SYSTEM.

The superiority of the arc light over all other systems of illumination for use in places where a large amount of light is required, has been known and generally recognized by experienced electricians. It is the cheapest artificial light known. The best results both by scientific tests and by the experience of practical users. Second, it is the safest light known, being wholly free from all danger of explosion, heat, escape, use of matches, etc., incident to gas, oil and other systems of lighting. The uniformity throughout the country have made a careful examination of the subject, and have in all cases manifested that lighting by this system is free from danger, when the apparatus is properly constructed and worked. The New York Board of Fire Underwriters has adopted regulations for the erection of plants, with which they carefully comply.

Third. It is a pure white light, in character closely resembling sunlight. All colors appear correctly the same by this light as by daylight. This is a point of great importance, where artificial light is used in factories, stores, dye-houses and other places in which it is desirable to distinguish colors.

Fourth. It is an agreeable and wholesome light. A single gas-burner consumes as much oxygen as is required by five or six persons for respiration, and the noxious gases and great amount of heat created by oil and gas lights are disagreeable and deleterious to health. The electric light does not depend on combustion for its illuminating effects, and, accordingly, does not vitiate the air, and the amount of heat produced is extremely small. The light produced by the Weston arc system is remarkably steady, free from flickering, and is soft and agreeable to the eyes.

Fifth. The immense quantity of light which can readily be produced by the arc system renders it possible to obtain a perfect general illumination of a workshop, store, or other large space within a less economically attainable by any other system of lighting. This is of great importance in manufacturing establishments where night work is necessary, as the work can be carried on with almost as much facility by the electric light as by daylight.

THE WESTON AND OTHER ARC SYSTEMS.

The Weston arc system differs from other arc systems now in use, not only in the construction of the apparatus, but in the character of the current used and in the quality of the light produced. The lamps are adjusted to work with a shorter arc or separation between the carbon pencils, and the mechanism used to operate is so constructed as to generate a continuous current of lower electro-motive force and greater quantity than any other systems. The not only obviates the danger of accidents to persons using the apparatus, but renders the light produced of better quality and of greater intensity for a given expenditure of power. While numerous fatal accidents have occurred from the use of machines producing an intermittent or pulsating current of very high electro-motive force, no person has ever been in any way injured by the current from a Weston machine. This remarkable immunity from accident is not by any means fortuitous, but is the result of the system itself. It may be well to quote here, in full, the report made by the committee above named to the Bridge trustees, for the important points of the company's system are there clearly stated by impartial and scientific men.

To the Board or Trustees of the New York and Brooklyn Bridge:

The undersigned, to whom it was referred by this Board to consider and determine what system of electric lighting was best adapted to the requirements of the Bridge, report as follows:

Representatives of the several lighting companies that had submitted proposals for lighting the Bridge appeared before the Committee at their meeting appointed for the hearing. The companies were the United States Illuminating Co., the Brush Swan Electric Light Co., the Edison Electric Light Co., the Fuller Electrical Co., the Schuyler Electric Light Co., and the Arnoux & Hochhausen Electric Light Co.

The Committee heard all that were present at considerable length, and made exhaustive inquiries as to the advantages claimed for the different systems represented. After careful consultation with Mr. Martin, Engineer of the Bridge, who had made an examination of the different systems in actual operation, it was decided to award the contract to the United States Illuminating Company. Although this company was the lowest bidder, the Committee was wholly influenced by this consideration in making its decision, but selected the system which the United States Company proposed to use as the one in all respects best adapted for the work of permanently lighting the Bridge in a satisfactory manner.

The proposal of the Edison Co. involved the use of incandescent lights, and was not favorably considered, as it appeared to the Committee that greater economy of power and more perfect general illumination would be obtained in the Bridge, by the use of powerful arc lights.

Of the different arc systems represented, the Weston system is used by the United States Co., and the Brush system used by the Brush-Swan Co., seem to present greater advantages than the others. Both of these systems are well known and have for a long time been in successful and very extensive use throughout the country, and the companies which are introducing them are doing a large business and have had great experience in carrying out installations similar to that desired for the Bridge.

While there seems to be little room for choice between the two systems in regard to reliability of the apparatus for continuous use, the Weston system appears, from the facts presented to the Committee, superior to the Brush in other respects, and especially in economy of power and in safety.

The engineers of the Bridge have carefully examined the Weston apparatus and are of the opinion that it is admirably designed and well constructed, and the large number of lights of this system which they have observed in operation on New York City appeared to be working in a very satisfactory manner.

It appears that local and momentary lights which have been made of different dynamo machines with reference to economy of power, and especially those conducted by the Committee appointed for that purpose at the Paris Electrical Exposition, show a considerably higher efficiency for this Weston dynamo than for the Brush or for any of the others which have been brought into competition with it; and it is stated by the representatives of the United States Co. that important improvements have been made in the Weston machine since those tests were made, which make its superiority in this respect still greater.

As the expenses of supplying power to operate the lights is to be borne by the Bridge corporation and will be continuous, any considerable reduction in the amount of power required appears to be a very material consideration.

In view of the numerous reports of fatal accidents occasioned by persons coming accidentally into contact with the wires of electric lighting circuits in which a current of very high tension is employed, the Committee inquired very carefully into the relative safety of the different systems submitted and from the facts elicited, is satisfied that the advantages of the Weston system in this respect are very marked. The Weston lamp is constructed to work with a very short arc or the separation between the carbon points (the length of the Weston arc being about 1-32 of an inch, while the arc employed in other systems is from 1-16 to 1-8 of an inch in length) and the tension of the current required for working a given number of lamps in the same circuit on the Weston is correspondingly low. The Weston current is also continuous and uniform, while in other systems, notably the Brush, the current is pulsating in its character; and all writers on the subject appear to agree that a pulsating current is more dangerous than a continuous one of the same tension.

As the Bridge is to constitute a great public thoroughfare and any defect of insulation or accidental disfacement of the wires might bring the iron work of the structures into the circuit, it seemed to the Committee to be highest degree objectionable to permit the use of such a current as would be capable of doing deadly harm. A current of very high tension, especially when it is pulsating in its character, appears to be peculiarly dangerous in this respect.

Of the systems examined, those of the Weston Co. and the Brush Co. are the only ones which have been in successful and extensive use for a long time, and which are known to be reliable. Both of these systems are well known to be reliable. Both of these systems are well and very extensive use throughout the country, and the companies which are introducing them are doing a large business and have had great experience in carrying out installations similar to that desired for the Bridge.

While there seems to be little room for choice between the two systems in regard to reliability of the apparatus for continuous use, the Weston system appears, from the facts presented to the Committee, superior to the Brush in other respects, and especially in economy of power and in safety.

The engineers of the Bridge have carefully examined the Weston apparatus and are of the opinion that it is admirably designed and well constructed, and the large number of lights of this system which they have observed in operation on New York City appeared to be working in a very satisfactory manner.

It appears that local and momentary tests which have been made of different dynamo machines with reference to economy of power, and especially those conducted by the Committee appointed for that purpose at the Paris Electrical Exposition, show a considerably higher efficiency for this Weston dynamo than for the Brush or for any of the others which have been brought into competition with it; and it is stated by the representatives of the United States Co. that important improvements have been made in the Weston machine since those tests were made, which make its superiority in this respect still greater.

As the expenses of supplying power to operate the lights is to be borne by the Bridge corporation and will be continuous, any considerable reduction in the amount of power required appears to be a very material consideration.

In view of the numerous reports of fatal accidents occasioned by persons coming accidentally into contact with the wires of electric lighting circuits in which a current of very high tension is employed, the Committee inquired very carefully into the relative safety of the different systems submitted and from the facts elicited, is satisfied that the advantages of the Weston system in this respect are very marked. The Weston lamp is constructed to work with a very short arc or the separation between the carbon points (the length of the Weston arc being about 1-32 of an inch, while the arc employed in other systems is from 1-16 to 1-8 of an inch in length) and the tension of the current required for working a given number of lamps in the same circuit on the Weston is correspondingly low. The Weston current is also continuous and uniform, while in other systems, notably the Brush, the current is pulsating in its character; and all writers on the subject appear to agree that a pulsating current is more dangerous than a continuous one of the same tension.

As the Bridge is to constitute a great public thoroughfare and any defect of insulation or accidental disfacement of the wires might bring the iron work of the structures into the circuit, it seemed to the Committee to the highest degree objectionable to permit the use of such a current as would be capable of doing deadly harm. A current of very high tension, especially when it is pulsating in its character, appears to be peculiarly dangerous in this respect.

Of the systems examined, those of the Weston Co. and the Brush Co. are the only ones which have been in successful and extensive use for a long time, and which are known to be reliable. Of the systems examined, those of the Weston Co. and the Brush Co. are the only ones which have been in successful and extensive use for a long time, and which are known to be reliable. Both of these systems are well known and have for a long time been in successful and very extensive use throughout the country, and the companies which are introducing them are doing a large business and have had great experience in carrying out installations similar to that desired for the Bridge.

While there seems to be little room for choice between the two systems in regard to reliability of the apparatus for continuous use, the Weston system appears, from the facts presented to the Committee, superior to the Brush in other respects, and especially in economy of power and in safety.

The engineers of the Bridge have carefully examined the Weston apparatus and are of the opinion that it is admirably designed and well constructed, and the large number of lights of this system which they have observed in operation on New York City appeared to be working in a very satisfactory manner.

It appears that local and momentary tests which have been made of different dynamo machines with reference to economy of power, and especially those conducted by the Committee appointed for that purpose at the Paris Electrical Exposition, show a considerably higher efficiency for this Weston dynamo than for the Brush or for any of the others which have been brought into competition with it; and it is stated by the representatives of the United States Co. that important improvements have been made in the Weston machine since those tests were made, which make its superiority in this respect still greater.

As the expenses of supplying power to operate the lights is to be borne by the Bridge corporation and will be continuous, any considerable reduction in the amount of power required appears to be a very material consideration.

In view of the numerous reports of fatal accidents occasioned by persons coming accidentally into contact with the wires of electric lighting circuits in which a current of very high tension is employed, the Committee inquired very carefully into the relative safety of the different systems submitted and from the facts elicited, is satisfied that the advantages of the Weston system in this respect are very marked. The Weston lamp is constructed to work with a very short arc or the separation between the carbon points (the length of the Weston arc being about 1-32 of an inch, while the arc employed in other systems is from 1-16 to 1-8 of an inch in length) and the tension of the current required for working a given number of lamps in the same circuit on the Weston is correspondingly low. The Weston current is also continuous and uniform, while in other systems, notably the Brush, the current is pulsating in its character; and all writers on the subject appear to agree that a pulsating current is more dangerous than a continuous one of the same tension.

As the Bridge is to constitute a great public thoroughfare and any defect of insulation or accidental disfacement of the wires might bring the iron work of the structures into the circuit, it seemed to the Committee to the highest degree objectionable to permit the use of such a current as would be capable of doing deadly harm. A current of very high tension, especially when it is pulsating in its character, appears to be peculiarly dangerous in this respect.

A current of very high tension, especially when it is pulsating in its character, appears to be peculiarly dangerous in this respect.

ELECTRICITY AND TELEGRAPHY.

THE COST OF ELECTRIC LIGHTING.

At the lecture delivered by Mr. J. W. Swan at the Royal Institution, on electric light, on March 10, the author chiefly dealt with its cost. Its directest bearing was admitted to be that of economy. The electrical illumination of incandescent carbon lamps had been so far developed that their use was economically practicable, though not yet universally introduced. The electrical heating to a slight degree of incandescence during 1200 hours did not destroy a well-made lamp, and the utmost limit of lamp's life might be they did not know. Probably it would be an excel-becoming span; as, with the present economy, processes of manufacture were sure to become more and more perfect. Taking it, therefore, as fully established that a cheap and durable lamp could now be made, the further question was as to the cost of the means of illumination. The cost of producing light by means of electric incandescence might be compared with the cost of producing the same light in the way, 1 cwt. of coal produced 10,000 candle-light per hour; 1 cwt. of coal produced a quality called different-candle-power, and a wider power candle light for one hour. But besides the product of gas, the coal yielded certain by-products of value, upon which the would, therefore, take it that they had to credit 1000 feet of gas from one cwt. of coal instead of 5000 as actually the case. The cost of coal would be 4d., and fifty-hours-power for one hour. Repeated and reliable experiments showed that they could obtain through the medium of incandescent lamps at least 200 candle-power per horse. But as there was waste in the conversion of motive power into electricity, and also in the conducting wires, he made a liberal deduction of 25 per cent. and took away 150 candle-light as the nett available product of one horse-power. Fifty horse-power, at the cost of 4d. per hour, would, therefore, produce 7500 candle-light, or against 10,000 candle-light, which was to say, against 1000 cubic feet of gas from one cwt. of coal instead of 5000 as from the same quantity of coal by the process of production at present in use, an allowance would be made in favour of the cost of renewal of lamps. There was no expense in connection with gas lighting in the way of the renewal of burners, globes, chimneys, &c. He could not say that the charges against electric lighting would equal the corresponding charges against electric lighting, unless they increased in a very much greater degree than he thought they would. Before leaving the question attention be given, for beyond what was formerly called the "first fifty horse-power," the cost of electricity would be the full "first light" produced when the first of gas, would be obtained. Taking that into account, he thought but little, if any, greater allowance would be made for the charge in favour of gas, when the question of saving in electric lighting through the renewal of expensive charges for renewal of glass burners, globes, chimneys, &c., fluid would become still greater, the cost of renewal of lamps would be relatively less. The cost of renewal of lamps would be relatively less. The cost of renewal of lamps would be relatively less. The

Engineering, Feb 24, 1882.

THE LAING ELECTRIC LIGHT.

A COMPANY has lately been registered under the above name, and is now making preparations for lighting Waterloo-place, Piccadilly-circus, and Regent-street, with twelve lights. The difficulty of finding a suitable position for the engine and machinery, usually a matter of great trouble in such a locality, has been solved with a simplicity that is astonishing by building a wooden shed for their reception in the centre of the roadway between the Crimea Monument and the Duke of York's Column. It is evident that even London vestry, at any rate, does not place needless obstructions in the way of scientific experiments. The company is one of which little is at present known, except that it has a nominal share capital of one million sterling, and that its system has been already tried on a small scale in France. There are, however, in the Patent Office three specifications of inventions in electricity commencing with the names of Bontellieux and Laing, Nos. 847 of 1880, and Nos. 3102 and 3214 of 1881, and unless we are much mistaken, these form part of the stock-in-trade of the new company, though how much they represent of their astounding capital we do not know. The first was filed-entered in our Patent Record of October 8, 1880. In it is shown a lamp having an upper carbon carried in the form of a tube enclosing a core of non-conducting material, such as was claimed by M. Jablochkoff in a supplement to his first patent (see ENGINEERING, vol. xxxii, page 256). The point of the lower carbon abuts against this core, and the arc forms between it and the cylinder around it, and is always of one constant length. The lamp requires no regulating mechanism, and the feeding of the lower carbon is effected by a weight or a spring. The third mechanism appears to be in part a development of the first, and aims at conducting to one lamp both an arc, as the term is usually understood, and a non-conducting shuttcock. One example somewhat resembles a Wilde candle. Two pencils, inclined at a slight angle to each other, abut at their upper extremities on the core of a tubular carbon towards which they are fed, as fast as they waste, by weights or springs. The arc is formed between them and the carbon cylinder, an electro-magnet, acting on their guides or slides, separating them and bringing them momentarily in contact with the cylinder when the arc fails. In another lamp an ordinary carbon pencil is employed as the lower electrode, and its upward feed is regulated by a spring brake opposed to a magnet in a shunt circuit. Provision is made that if all the current passes through the shunt, as it would do if the light were extinguished, that it shall lift the lower electrode out of the annular carbon and the circuit is re-established. The non-conducting core appears to be held in reserve and only to come into use in operation when worthy of remark that the new specification does not follow the usual method and refer to the previous one, but reproduces it in full with slight alterations, and also appears to claim the previous invention as well as the present one, a method of "making assurance doubly sure" that is not without its drawbacks in patent matters. The remaining invention relates to the use in conjunction with magnets or dynamo-electric machines of a commutator working in water or other fluids of little or no conductivity. The specification contains no drawings, as it is the principle rather than any particular method of putting it into operation that is claimed. The object is to prevent, or to mitigate, the disruptive action of the spark that occurs as the successive plates of the commutator pass under the brushes, by isolating them from the oxygen of the atmosphere. It is very much to be doubted whether the expectation of the inventors will be fulfilled; there will certainly be no greater resistance to the secondary currents in the water than in the air, and as they spring from plate to plate, or from plate to brush, they will probably carry particles of metal with them, whether they be oxidised or not. The copper dust that falls so plentifully from the commutator of an over-driven machine shows but little evidence of oxidation. It might at first sight be imagined that the cooling effect of a liquid envelope would prevent the formation of the sparks, but, seeing that with a little trouble an ordinary arc lamp may be made to burn satisfactorily under water, even when the latter is in a state of great agitation, it does not appear probable that this cause would be of much avail against the minute arcs in question. The invention, whatever may be its merits, is not entirely a stranger to the Patent Office. In 1854, C. F. Varley patented an electro-meter, with regard to which he said: "In order to prevent the burning of the parts where contact is made and broken I surround them with oil or any suitable hydro-carbon, or other matter for gas, which excludes the presence of oxygen; or I extract the air from the chamber surrounding them. I am aware that it has been before proposed to employ oil or naphtha about the contact surfaces of, but, therefore, claim this principle, but I find it to be usefle in all cases to employ it." Again, in 1877, MM. Gramet and Varvin, of Paris, described an electro-magnetic engine in which reciprocating rods slipping into mercury cups distributed the current, and water or other non-conducting liquid was placed in the cups above the mercury for the purpose of extinguishing the spark that resulted from the rupture of the circuit. It may be, however, that Messrs. Bontellieux and Laing have been more successful in their experiments than would appear from their specification, and we shall await their exhibition of their apparatus with interest, as there is no doubt that commutators are the most troublesome parts of electric light machinery.

Engineering, March 2, 1883.

ELECTRIC LIGHTING NOTES.

In our last week's issue, on page 178, and again in this on page 188, we have devoted considerable space to an explanation of the construction of the Brush secondary battery, and of the current manipulation by which it is governed. Just before Christmas the Brush Company of New York announced that they were ready to supply these batteries to persons residing along the line of the mains used by them to street illuminants. It was stated that the generator which had hitherto been driven during the daylight, should be employed during that time in charging those batteries with a store of energy, that would be available for feeding local installations of incandescence lamps in the evening. In order to do this it was necessary that the arc lamps should be disconnected from the mains, and the mains coupled to the battery circuits before the charging could cause one, and for this purpose the expedient was adopted of reversing the current when it was transferred for one use to another. By this means and the use of "shorting" constructed after the manner of pole-changers, the current is directed to either of the two sets of apparatus in which it is to be utilised.

The sizes and capacities of the batteries are given below:

Size of Cells.	Capacity in Swan Lamps.	Size of Plates in Inches.	Number of Cells for Swan Lamps.
No. 2	10 to 8	8 × 8	20
„ 2	20 „ 15	8 × 10	20
„ 3	26 „ 30	8 × 10 } [Double]	20
„ 4	40 „ 60	10 × 10 } [Double]	20

At an exhibition in New York, 27 Swan lights and a one horse-power motor were shown in action fed by a box of batteries measuring 3 ft. by 1ft. by 10 in. The means whereby the main current is delivered to the batteries, until such is fully charged and is then switched off, will be found illustrated and explained in detail at page 190.

Assuming further, since all the quantities are small, that when the jackets were set in use there would be the same amount of radiation as when they were, we have the following results:

Condensation per Stroke.	Pounds.	Thermal Units.
In steam pipe	.0026	0.7
Non - condensing cylinder valve chest	.0008	0.8
Non-condensing cylinder ends ...	.0016	0.2
,, ,, barrel ...	.0009	0.9
Condensing pipes and receiver ends ...	.0009	0.6
Receiver sides	.0019	1.7
Condensing cylinder valve chest ...	.0003	0.3
,, ,, ends ...	.0007	0.4
,, ,, sides	.0022	2.2
Total in steam pipe and high pressure valve chest ...	.0031	7.5
Total in cylinder and receiver ...	.0071	6.0

On the other hand, a certain amount of heat will be discharged by the friction of the valves and pistons. Assuming the power of the engine to be 100 indicated or 15-horse power, the quantity of heat would be 4.2 thermal units per stroke. Hence we may assume that the loss by radiation from the cylinders was balanced by the heat equivalent of this friction.

Now let w be the weight in pounds the percentage of water in the steam supplied to the engine, let:

f be the number of pounds of vapour delivered to the engine per stroke;

T its temperature in degrees Fahrenheit.

q the number of thermal units in 1 lb. of water at temperature T.

If the number of pounds of water discharged from the jackets be f_1,

t the number of pounds of steam, and y the number of pounds of water contained in $V = 1$,

$x + y = 772$ the equivalent in thermal units of the number of foot-pounds of work done per stroke.

l the number of pounds of injection per stroke.

t_1 t_2 t_3 the temperature in degrees Fahrenheit of the injection, ejection, and feed to economiser.

Then the heat received by the engine is:

$$x(1114 + .305T) + y\,q,$$

and the heat accounted for by the engine is:

Heat converted into work,

$$2\,p + 0.772.$$

Heat discharged from the condenser after deducting that received in the injection water,

$$l\,(t_2 - t_3) + .5\,t_2,$$

heat supplied to feed water in passing through coil in exhaust pipes

$$(1{\cdot}4\,D) - (t_2 - t_3),$$

heat discharged from jackets

$$D\,t_1.$$

Whence assuming the heat lost by radiation from the cylinders and receiver to be equal to that produced by the friction of the valves and pistons, and rearranging that $x + y = 772$:

$$x = 2\,p + 0.772 + l\,(t_2 - t_3) - .2\,(t_2 - t_3) + (1{\cdot}4\,D)\,(t_2 - t_3)$$

Consider the data for Tuesday, 31st October:

$M = 0.3313$	$M + D = 0.6021$.
$m = 0.2748$	$\Delta = 221$.
$l = 18.52$	$t_2 - t_3 = 11.17$.
$d = 2.25.77$	$p = 14.1$.

$x + y = 772 = 141.85 + 18.52 \times 11.17 - 0.2 \times 11.17 + 0.6021 \times 14.1$

$= 772$.

$y = 0.0021$ lb.

But the total weight of water supplied to the boiler per stroke was $0.6021 - 0.0221 = 0.5800$ lb., and the weight of this vapour produced was $0.3313 - 0.0221 = 0.3092$ lb., of which, as we have seen in the previous note, 0.0071 lb. was due to condensation in the steam pipe, leaving 0.3021 lb. as the weight of water carried over from the boiler, or less than 0.5 per cent.

Proceeding in this way, the following Table may be formed:—

	Oct. 25.	Oct. 26.	Oct. 27.	Oct. 28.	Oct. 31.	Nov. 1.	Nov. 2.
Weight of steam and water used per stroke	0.6241	0.5757	0.5292	0.5013	0.4787	0.4921	0.5021
,, dry steam in ditto	0.3313	0.3112	0.3107	0.3021	0.2748	0.2992	0.2992
,, water in ditto	0.2139	0.2072	0.2185	0.2132	0.2039	0.2052	0.2029
Condensed in steam pipe	0.0071	0.0074	0.0078	0.0071	0.0072	0.0074	0.0076
Brought over from boiler	0.3021	0.2702	—	0.2113	0.2076	—	0.2013

It will be seen that on every days the assumed weight of steam condensed in the steam pipe is greater than the calculated quantity of water in the steam delivered to the cylinder. Indeed, on the 27th of October the calculated weight of dry steam exceeds the weight of water supplied to the boiler, which is impossible. This anomaly, of course, arises from inaccuracy in the data from which the calculations are made, or, in other words, from errors of observation. The excess however, is only

$$0.2723 - 0.2677 = 0.0037,$$

or 0.57 per cent.

0.5307

The wettest steam seems to have been produced on the 26th of October, when the quantity of moisture was to 0.0123 lb., or nearly 1.53 per cent. This, however, is but little more than might be attributed to errors of observation, and, therefore, for the whole of the trials, as far as they go, it will be observed that the boiler produced very dry steam which, owing to loss of heat by radiation, became vapour containing per cent. of moisture by the time it reached the cylinder.

Note 1.—To explain the formation of Table I., consider the experiment of the 2nd of November. Tables XI. to XIV. show that the feed water used was 7.251 times as heavy as 44,770 lb., the weight of coal burnt as 350 lb., of which 481 lb. were ash; the indicated horse-power 282.5, and the total 2825.25. The water used per indicated horse power per hour was therefore

$$\frac{44{,}770}{7.251 \times 2825.25} = 17.10\ \text{lb.}$$

And as the steam held 1 per cent. of moisture when it reached the cylinder, the weight of dry saturated steam used per indicated horse power per hour was 17.10×0.99 = 16.929 lb. The other figures may be found in the same way.

In calculating the number of thermal units rejected per indicated horse power per minute, the heat put into the feed water as given in line 3 of Table II. must be added to the heat put into the injection water.

Note 2.—The following explanation shows how Table II. is formed. Take the data of 29th October. The feed per hour = 7.251 × 2825.25 = 20,490 lb. This, however, is at a temperature of 212.2 deg. (as shown by line 12 in thermal units is a pound, while 0.06031 thermal units as water, containing only 237.0 units per pound.

The total heat supplied to the engines was therefore—

In dry steam ...	= 0.9370 × 1210.8 =	1122.39 units.
In water... ...	= 0.0093 × 237.0 =	2.09 ,,
Total ...		1124.48 ,,

Again, the injection water used per stroke was 16.25 lb., and its rise in temperature 79.31 deg.—27.41 deg. = 51.9 deg.; therefore the heat received by it was 16.25×51.9 = 843.71 units. The feed per stroke was 0.6339 lb., and its rise in temperature in passing through the coil in the exhaust pipe of the condensing cylinder 119.39 deg.—27.41 deg. = 91.98 deg.; therefore the heat received by it was 0.6339 × 91.98 = 58.31 units. The water discharged from the jackets was 0.0442 lb. per stroke. In the condenser it became water at 90.31 deg., and therefore contained 0.0442 × 90.31 = 3.99 units. And lastly, the water received from the steam jackets was 0.0662 lb., while the temperature at which it was condensed and left the jackets was 328.5 deg.; therefore the heat carried off by it was 0.0662 × 328.5 = 21.75 units. The total received from the boiler was therefore 843.71+ 17.85+60.31+21.85=978.58 units. Thus the difference between this and the heat received by the engines, or the heat available for conversion into work, was 1124.02— 978.58=145.44 units. The actual work shown by the indicator diagrams was 109,085 foot-pounds per stroke, which is equivalent to 141.30 units, which differs from the latter found above by 4.31 units, or less than 3 per cent. of the total heat supplied.

Note 3.—With the aid of the explanations given in Note 2, and on page 20 of the report, the formation of Tables IV. to VII. will be easily understood. The data required will be found in lines 5 to 17 of Table XI., and in lines 2 to 12 of Table XII.

Note 4.—The relation between the change of the internal heat, the work of the expansion, and the heat supplied, is stated as in this way. For the sake of simplicity, suppose the steam to expand in a single vessel without receiving heat from or giving heat to the surfaces in contact with it, and let us divide the total expansion into three periods, and consider each separately. In the first period, let the internal heat fall from U_1 to U_2, and let the work done be called W_1; then

$$W_1 = U_1 - U_2.$$

Now let a certain quantity of heat, Q_2, be added, and let the steam continue to expand till the internal heat becomes U_3, then W_2, the work done during this period is given by

$$W_2 = U_2 + Q_2 - U_3.$$

At this point let a quantity of heat, Q_3, be taken from the steam, and let the expansion continue till the final internal heat U_4 is reached, then the work due to this change will be

$$W_3 = U_3 - Q_3 - U_4,$$

and the total work done during the whole expansion will be

$$W = W_1 + W_2 + W_3 = U_1 - U_2 - (U_3 - Q_2 - U_3 - U_4). \quad (1)$$

But the total work done is quite independent of the number of vessels in which the expansion takes place, and therefore if the steam be expanded in the most perfect manner, however complicated they may be, provided the initial and final internal heats are given out by the condensing surface. We may, therefore, apply the relation found above to the compound engine, with it will readily be seen that U_1 and U_2 are the initial and final internal heats in the cylinder, Q_2 the heat put into the steam by the jacket round the cylinder, U_3 the final internal heat in the receiver, Q_3 the internal heat of the steam conveyed away, and U_4 the heat equivalent of the work of the compression, the work done will be exactly the same as in the single cylinder.

Further it is evident that if we remove the restriction concerning the interchange of heat between the metal and the steam, the form of the right-hand member of equation (1) will be unaltered. The left-hand member, however, will contain a new term $E - H$, which is the difference between the heat lost by the metal at the beginning and end of the expansion, when the changes of the internal heat now corresponds, not only to the work done, but also to the gain or loss of heat by contact with the metal. Therefore, for the actual conditions under which the engines work, in other words, the work done, the heat received, and the change of the internal heat are connected by the relation

$$W + E - H = U_1 - U_2 - (U_3 - Q_2 - U_3 - U_4).$$

INCANDESCENCE LIGHTING.*

By J. W. Swan.

(Concluded from page 212.)

THE high electrical resistance of platinum, and its high melting point, mark it out as one of the most likely of the metals to be useful in the construction of incandescent lamps. When platinum is united with ten or twenty per cent. of silver (platinum silver is formed), which has a much lower melting point than platinum; and many attempts have been made to employ it in the form of electric lamps. But these attempts have not been successful, although as platinum has as the melting point of brick-platinum, it is not hot enough to allow of its being heated to a degree that would yield a sufficiently large return in light for energy expended. Besides, as temperature is raised, platinum becomes brittle and loses its resistance and breaks. This is a fatal fault, because the moment a wire breaks in a circuit there is the greatest possible advantage in having as low as least the incandescing body in an extremely high temperature. Then the tenacious action when it is resuscitated by a strong current is required to raise a wire to a cream red heat, and when this has been attained, it melts instantly (p. 214). The power absorbed in passing the leak up to that point is thrown away in any system of lighting in which it occurs. If the current which made the wire red-hot, be doubled in quantity, the wire will become white-hot, and then it will melt an appreciable amount of light. I will illustrate this by experiment.

It will be observed that a considerable amount of current is required to heat the wire up to the temperature at which it begins to emit light, and that when that point is reached the current must be increased to increase the production of light. One unit of current passed through the filament will only make it red-hot. It is at once regarded light. If the current be doubled, the light is at once raised to that of some four candles. But one unit cannot current at once raises the light to no less than forty candles.

The next important consideration is the fact (I have shown that it is essential to economy that the incandescing material should be able to bear an enormous temperature without fusion. We know of no metal that fulfils this requirement; but there is a non-metallic substance which does so in an eminent degree, and which also possesses another necessary quality, that of low conductivity. The substance is carbon. In attempting to utilise carbon for the purpose of incandescence, I have several serious practical difficulties to encounter. The first is that carbon is very combustible and difficult of fusion in its infusible. Carbon, as we commonly know it, is a brittle and non-elastic substance, possessing neither ductility nor tenacity to fit it for being shaped suitably for use in an electric lamp. Yet, in order to make it serviceable, it is necessary that it should be form it into a slender filament, which must possess sufficient mechanical strength to enable it to be being firmly attached to conducting wires, and to prevent its breaking. If tested while hot in the air, however, it will be found that the mechanical strength of an electric lamp. It is only while the hot three or four hours that these difficulties can be said to have been surmounted. It is now found that carbon can be produced in the form of straight or bent filaments of extreme slenderness, and possessing a great degree of elasticity and strength. The process by which this is effected is very simple—by the carbonisation of paper, and subsequently of woods and grasses. Excellent carbon filaments can be produced from cotton, from bamboo, and from cotton thread treated with sulphuric acid. The sulphuric acid treatment is necessary, as it gives to the cotton thread or paper which it acts on paper in the process of making parchment paper, and which is found to be necessary in making carbon filaments. In carbonising these materials it is of course necessary to preserve them from contact with the air. This is done by surrounding them with charcoal.

Here is an example of a carbon filament produced from cotton thread. It is about 0.02 inch in diameter, and less than 20 of an inch long. Another, and yet a length of three inches, having therefore a surface of nearly the one-tenth of an inch, gives a light of seventy candles when made incandescent in a moderate degree.

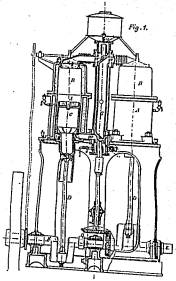
I have said, that in order to preserve these slender carbon filaments from combustion, they must be placed in a vacuum. Experiment has shown that if the vacuum be at all durable, the vacuum must be a very high one. One of the chief causes of failure of the carbon filaments is due to the presence of carbonic acid, and the imperfection of the vacuum in which the carbonising operation is performed. The presence of this gas in the filament when it is placed in a vacuum due to the production of a better vacuum in the lamps.

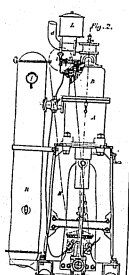
In the pistolite lamps, the glass globe or globe which enclosed the carbon filament was large, and usually had three joints, with leading-in wires passing through them. These joints were troublesome things to have with accuracy, and it was found necessary to make the glass globe as small as possible, and as as to have a vacuum like that at the upper end of a barometer, or the air was

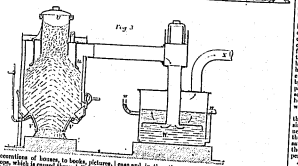
* Paper read before the Royal Institution.

SIEMENS' GAS PRODUCER AND MOTOR.

(*For Description, see Page 271.*)







furnishings and conditions of houses, to books, pictures, and to goods in shops, which is essentially destructive. Such a system would require a large expenditure for repair, and a large annual loss which is irreparable.

I have heard discussions of cost of electric light, power is 100 candles. But a knowledge of the latter is not to be considered, and it is impossible of the former had been obtained. The question of an abstract question how much light can be obtained from the motive power developed from ascertained fuel, how much, without much increased cost of light as obtainable by the operation of various means. I might have suggested that even more than double the light for this expenditure. Certainly double and beside the fact that this expenditure would be obtained. The fact which I have supposed can be obtained with long life in the lamps, and there would be a great difference of power, if we take more hours of light for this expenditure of power, or if we take more light for a shorter expenditure of power, or if we have a higher degree of incandescence with a proportionately greater expenditure of power. It is on this point which I have to make my comparison with the electric light.

In comparing the cost of producing light by coal and by electricity, it is essentially that with the rudest form of coal in electric lighting is only dependent on the skill and care of the chief source of expense in all the processes of gas also. When, however, as in the case of electric lighting power is in a position of still greater advantage, and in point of cost, altogether beyond comparison with other means of producing light.

To complete the comparison between the cost of electric light and gas light, we must consider not only the amount of coal required to yield a certain product of light in the one case and in the other, but also the cost of converting the coal into electric current and into gas; that is to say, the cost of manufacture of electricity and the cost of manufacture of gas. I cannot speak with the same exactness of detail on this point, as on the same exactness of detail on the cost of the raw material. But if you can state the exact cost of the gas manufacture, and that is the failure of the process through the loss of coal by natural labour processes, in so far as the quality of the clothing of a steam boiler, and if electricity generated by means of steam, then that if electricity is chiefly involved in both processes is not only the coal labour that in gas manufacture it would be necessary to clean into the furnaces and retorts free or at times as much coal have to yield the same light as it would be under the latter, in which case engine and dynamo-element lamps. But labour is necessary to attend to the engine and dynamo, labour is required in the products other than gas, and to half—i.e., that is, it will be only half the cost of labour in the case of gas. But when in our calculation we have charged gas with only one half the cost of labour which electricity can, in fact, have to bear. But when in respect of labour in favour of electricity there is chiefly in favour of the cost of gas, but it is well known that labour products of gas, and that can be obtained for gas.

With regard to the cost of coal, I am aware that gas works are even better situated than electric lighting stations in respect to railways and furnaces, justifying standing charges, and establishments, and appliances for distribution. Plant for generating electricity on a large scale would consist chiefly of boilers, steam engines, dynamo-electric machines, and batteries for storage.

No such electrical station, on the scale and in the completeness of arrangement which I have supposed, has yet been put into actual operation; but several small stations for the manufacture of electricity already exist in England, and three large stations, one by Mr. Edison here, if I am rightly informed, almost completed in America. We are therefore on the point of ascertaining by practical experience, what the cost of the works for giving the electricity will be. Meanwhile, we know precisely the cost of coal to steam engines, and we know approximately what ought to be the cost of dynamo-electric machines of suitably large size, and we have, therefore, sufficient grounds for concluding that to produce a given quantity of light electrically the cost of coal will not exceed greatly, if at all, the cost of equivalent gas light.

There remains to be considered, in connexion with this part of the subject, the cost of distribution. Can electricity be distributed as widely as gas? On one condition, which I fully have not yet accomplished, this may be answered in the affirmative. That condition is that it be found practicable and safe to distribute electricity of comparatively high tension.

The importance of this condition will be understood when it is remembered that to effectively utilise electricity in the production of light in the manner I have been explaining, it is necessary that the resistance in the carbon of the lamps should be relatively great to the resistance in the wires which convey the current to the lamps. When lamps are united with the conducting wire the current divides, which it conveys is divided amongst them, you have a considerable strength in which aggregate resistance of the lamps will be small, and the conducting wire, to have a relatively small resistance, must either be very short, or, if it be long, it must be very thick, otherwise there will be a waste of much energy; in fact it would not be a practical condition of things.

In order to supply the current to the lamps economically, there should be comparatively little resistance in the line. A waste of energy through the resistance in the wires of over perhaps 20 per cent. might be allowable, but not much beyond. Coupled in the lamps in the manner I have described—that of multiple arc, each lamp being as it were a conducting bridge across main wires, there—even if the individual lamps offered a somewhat higher degree of resistance than the lamps at present in use—the thickness of the conductor would become enormous if the line was far extended. In a line of half a mile, for instance, the weight of copper in the conductor would become so great, in proportion to the number of lamps supplied through it, as to be a serious charge on the light. On the other hand, if a smaller conducting wire were used, the waste of energy and consequent loss would greatly exceed that I have mentioned as the permissible limit.

Distribution in this manner has the merit of simplicity, it involves no danger to life from accidental shock; moreover it does not demand great care in the insulation of the conductor. But it has the great defect of limiting within commercially small bounds the area over which the current for lighting purposes can be distributed from one centre. In order to light a large town electrically on this system, it would be necessary to have a number of separate stations.

There is a mode of supply of power, however, which effects a wider distribution practicable to be able to do so. Arranging the lamps in series, so that the same current traverses through several lamps in succession, by means of several short coils, placed as electric resistance in each lamp, it would be possible to economically obtain a much wider distribution.

Whether by the method of multiple arc which necessitates the multiplication of electrical lines, or by means of the series system, or by means of secondary batteries conveyed with each other from house to house, or by other means, satisfactorily being fed from these in multiple arc or quite practicable and economically with the distribution of power of its power of electricity is sufficiently economical for general application on a large scale.

As to the cost of the electric light, I have it on the authority of Sir William Siemens, who has just had his house completely fitted with incandescent lamps, that the cost of internal wires for the electric lamps is so small—that the cost of lighting will

THE LIGHTING OF THE SAVOY THEATRE.

The general adoption of the electric light for the illumination of theatres and other places where large numbers of persons congregate, cannot be very much longer delayed, because it fulfils every requirement for perfect lighting, and when properly carried out is free from nearly all the dangers and defects which appear to be inseparable from all other systems of illumination.

The lighting of a theatre, however, involves the fulfilment of conditions peculiar to itself, and which differ in very essential qualities from all other installations, and it is not too much to say that any system of illumination which is applicable to the lighting of a high-class theatre can be successfully applied almost anywhere, for there is no installation which can furnish so severe a test for any given system. Let us see then what are the peculiar requirements to be fulfilled in the lighting of a theatre. In the first place the auditoriums of theatres are, for obvious reasons, not provided with windows, and thus they are at once deprived of the principal means of ventilation and circulation of air, both of which other buildings can have the advantage. It is, therefore, highly important that an illuminating agent should be employed which does not in its action overheat the air, and above all which is incapable of vitiating the atmosphere by continually pouring into it the poisonous products of combustion that are inseparable from every system of illumination except that of electricity.

Another requirement of theatre illumination is the production of a well-distributed, brilliant, and pure light, one which is completely under control, and can be regulated at will from the stage. This requirement is fulfilled with very considerable success by gas, but, on the other hand, gas illumination cannot be conjured from the wondrous artificial light with any of the incandescence systems of electric lighting.

Many who have never been behind the scenes at a theatre are under the impression that the principal source of illumination for the stage is the row of footlights, and perhaps a few gas jets immediately behind the proscenium, but in order to obtain adequate illumination for the various scenes, the stage of every theatre is provided with long rows of gas jets above the backs of the scenes and behind almost every layer of scenery, as well as a corresponding number of vertical columns of lights behind the "wings," and no one can stand behind the scenes when matters are being struck with any amusement that it is possible to run a piece for many nights together without the theatre being burnt to the ground, for the whole surroundings, above, below, and on every side, appear to be one vast naked gas jet, and scenery composed of the most flimsy and inflammable materials, the two supporting almost to come into contact at every draught of air. As a matter of fact, however, the flames are rarely allowed to be covered with wire netting, by which the scenery is kept out of the flames, but the comparative rarity of fires at theatres is a proof that managers and their responsible agents are very careful in the handling of so dangerous a combination. It is therefore impossible to over-estimate the importance to the lighting of a theatre, and especially the stage, of employing a system of illumination which is practically a perfect

* See ENGINEERING, vol. xxxiii., page 417.

safeguard against fire. We have referred to the comparative rarity of fires in theatres, but this rarity is unhappily only comparative, and must be considered rare only in connection with the dangerous combination of gas jets and inflammable material, which until lately was necessarily inseparable from the stage of a theatre. When, however, a fire does occur during a theatrical performance, it is too often awful in its character, and the fatality which accompanies it, and the recent disasters at Nice and Vienna have not only moved the public and the authorities in all countries to consider the safety against fire of theatres, and other similar places of amusement, but theatrical managers have all, for more reasons than one, been awakened to the importance of attending to this all-important question.

In the autumn of last year some highly interesting experiments in connection with the Exhibition of Electricity were made at Paris on the electrical illumination of the Grand Opera, and were described in these columns at the time.* These experiments excited very considerable public interest, and constituted the first practical indication that the light of the future for theatre illumination must be in a degree electricity.

Almost simultaneously with the establishment of the experimental installations at the Paris Opera, Mr. D'Oyley Carte, the enterprising proprietor of the new Savoy Theatre, in London, determined to light this charming little theatre by the Swan incandescence electric light, and the work of installation was entrusted to Messrs. Siemens Brothers and Co., who appointed one of their electrical staff, Mr. C. Kingdon, to carry out the work on their behalf. The theatre is to be lighted by not less than 1158 Swan lights of the improved form recently introduced by Mr. C. H. Gilbert, one of the Swan Electric Light Co.'s engineers, who has adopted it as their most improved pattern, and these 1158 electric lights the auditorium is lighted by 114 lamps attached in groups of three, supported on very elegant threefold brackets projecting from the different tiers and balconies, each lamp being enclosed within a ground, or opaline shade, by which arrangement a most soft and pleasant light is produced.

Fig. 1 (see next page) is a view of one of these bracket lamp holders, which have been designed and constructed by Messrs. Faraday and Son, of Berners street, London. Two hundred and twenty lamps are employed for the illumination of the numerous dressing-rooms, corridors, and passages belonging to the theatre, while no less than 824 lamps are employed for the lighting of the stage.

The stage lights are distributed as follows:

6 rows of 100 lamps each above the stage			600
1	„ 16	„	16
1	„ 18	„ fixed uprights	18
5	„ 10	„	50
2	„ 10	„ ground lights	20
2	„ 11	„	22
			824

And in addition to the above-mentioned lights within the theatre, there are eight pilot lights within the engine-room, which serve the purpose of illuminating the switchboard; and as they are in the same circuit with some of the lights in the theatre, they indicate to the engineer in charge of the machines, by the changing of their illuminating power, when the lights on the stage are turned up or down. The new form of Swan lamp employed in this installation is shown in Figs. 2 and 3, and is both simpler and neater than the lamp of the same company of earlier construction, and, moreover, can be turned out more rapidly and at a cheaper rate. By this new arrangement the very objectionable and unsightly flattage of the old lamp is entirely dispensed with, and the exterior of the lamp is entirely of glass, having two very small platinum loops protruding from the lower part of the neck and which form the terminals of the carbon filament within the lamp. The fitting by which these lamps are attached to the brackets is illustrated in Fig. 3, and is of the simplest possible construction, consisting merely of a small cylindrical button of ebonite which by a screw above below the figure can be attached to the brackets or may be screwed into any ordinary gas fitting in the place of the burner. In the upper surface of this button are inserted two little platinum hooks communicating with the two small metal screws, and these hooks are fixed at a distance apart equal to that of the little eyes or loops of the lamp, and which, when the lamp is in its place, are hooked over them, the two long metal springs which form the electrical contact by the spiral brass spring shown in the figure, and which is set up by the shoulder of the glass envelope of the lamp.

The lamps are so placed in the various branch circuit in six groups, five of which comprises two hundred lamps each, and the fifth one hundred and sixty-six lamps. The current of each group is produced by one of Messrs. Siemens Brothers' W, alternate current machines, illustrated in Fig. 5, with field magnets of which are excited by a separate dynamo-electric machine of the Siemens type, known as D, and which is in general form similar to that shown in Fig. 4. The machines and engines are fixed in a shed erected on a piece of waste land adjacent to the Victoria Embankment, the current being conveyed to the theatre by means of insulated cables laid beneath the soil.

The six alternators or W, machines are driven at a speed of 70 revolutions per minute, and the six D machines at 1150 revolutions, by three steam engines, that is to say, a portable 20 horse engine by Garrett, a 12 horse power portable by Marshall, and a 20-horse semi-portable engine by Robey, but the horse power actually utilised is measured by a Hefner von Alteneck dynamometer, is but seven 120 and 130 horse power, as it was not, however, easy to state, that in addition to the six pairs of machines for working the 1166 incandescence lamps there is also a D, Siemens dynamo machine for producing the powerful arc electric light suspended outside the theatre, and over the principal entrance, and that the power to drive this machine is included in the above mentioned horse power employed.

The most interesting feature, however, from a scientific point of view, of this most interesting installation is the method by which the lights in all parts of the establishment are under control, for they are all under the control of an attendant turned up to their full power or gradually lowered to any desired level, as easily as if they were gas lamps, by the simple turning of a small handle. There are six large regulating handles—corresponding to the number of the machines and circuits—arranged in a row against the wall of a little room or rather closet on the left of the stage, and each of these is fixed on the end of a screwed shaft which, by throwing into its corresponding support circuit, greater or less resistance (increasing or decreasing it in six stages), the strength of the current passing through the lamps in the circuit is increased by so many grades. The special interest of this part of the installation, however, is the fact that the turning down of the lights is accomplished by a corresponding weakening of the power in the engine, for the variable resistance which is controlled by the regulating handle is thrown into the external or lamp circuit of the alternate current machine, which is the current generator, and thus the field magnets are excited. When a series of lights is lowered, increased resistance is thrown into the circuit of the dynamo machine, which is exciting the magnets of the alternate current generator corresponding to that particular series of lights, and the intensity of the magnetic field of the latter machine is thereby reduced, and consequently the current induced in the coils of that field and transmitted to the lamp circuit are diminished in strength; but by the weakening of the magnetic field the mechanical resistance to rotation is correspondingly reduced, and therefore less power is required to drive the machine. This very beautiful arrangement is at present applied to four of the six circuits, but from its very successful working it will probably ere long be applied to the other two with a corresponding increase of working economy. The resistance thrown into the circuits are at present of two sorts; the four switches, to which we have just referred, transmit the exciting current into long spirals of iron wire supported on a frame and having a free circulation of air around them by which the heat generated by the current is rapidly dissipated, and the switches of the other two circuits operate in a similar way upon resistance composed of zig-zag bands of loop iron similarly arranged. It has occasionally been put forward by persons who have interest in it to oppose the introduction of electric illumination, that lighting by electricity is accompanied by two sources of danger, the one that of causing fires through improper contacts or over-heating conductors, and the other that of the giving of dangerous shocks to persons who touch or handle the wires. These objections to electric lighting have just that substratum of truth in them which makes it necessary to refer to them, and also to explain what they mean. It cannot be denied that fires have been caused by badly laid or badly constructed electric light conductors, and this occurred more than once at the Exhibition of Electricity at Paris, and it is also well known that occasional accidents have occurred from shocks received from some of the higher electromotive force machines. We venture, however, to affirm without the slightest fear of intelligent contradiction, that there cannot exist the very smallest fear of fire occurring in an installation of incandescence electric lighting if the conductors are properly constructed, and just up by a person who understands the business, and the same remark applies with equal force to the question of the danger of electric shocks (but this element of danger is absent in the machines which are employed in connection with the Swan system), and we would also venture to say that no accident arising from either of these causes is to be apprehended in an incandescence installation of a slightly more extensive character than that of the theatre for an illustration so far as unsafe conductors, that there is for a gas-fitter to lay a leaky or otherwise defective gas-pipe, which would be attended with still greater certainty of disaster. In all industries electric competition is certain to lead to inferior articles being manufactured in order to reduce estimates, and the business of the electrical engineer is no exception to this liability, but we would venture to point out that the employment of inferior conducting cables for electric light transmission is the very falsest of economy, for, in the first instance, it might lead to serious results for reasons given above, and in the second, the installation could not be worked through such conductors with a proportional loss of current, and therefore of motive power. We do not think it is too much to say that, with but very few exceptions, if any, all the accidents which have occurred, either of fire or of serious shocks in electric light installations, may be traced to faulty construction or improperly-laid conducting wires. With the splendidly constructed cables of Messrs. Siemens, accidents of this description are practically impossible, and we would also point out that it is part of the Swan system as it is of that of Mr. Edison, to make use of little fusible safety strips at various points in the circuit, so that if from any cause there occurs any liability for the conductors to become overheated the current is instantly interrupted; this is, however, unfortunately no remedy to guard against a danger which is next to impossible to occur in practical working, but incandescence lighting from dynamo-electric machines is a powerful a current being transmitted through them. In every article and among points after nothing could be more completely successful than the incandescence lighting of the Savoy Theatre; the illumination is brilliant without being dazzling, and while being slightly whiter than gas, the sensation of "ghastliness," so often urged against the light of the electric arc, is in no way to be applied. In addition to this the light is absolutely steady, and thanks to the exertions of Mr. D'Oyley Carte, it is now possible for the public to go to the Savoy of an evening for the theatre to sit for a whole evening and enjoy a dramatic performance in a cool and pure atmosphere.

NOTES.

THE JABLOCHKOFF LIGHT AT THE CRYSTAL PALACE.

THE Compagnie Générale d'Electricité is making a very fine display at Sydenham, and pending by the completion of the Paris Exhibition has judiciously divided the collection of lights into groups with separate sources of power. These groups includes the lighting of the low-level station at the Crystal Palace, of the Joseph Brotherhood, and of the Canal Railway Company. This is very efficiently arranged for lighting the latter scene entirely, fed by two Gramme generators driven by a 15 horse power portable engine by Messrs. Ransomes, Sims, and Co., of Gainsborough. This installation is arranged for lighting the latter scene entirely, and is attended to by one man. The western gallery of the Palace is lighted on Jablochkoff system under various adaptations, which include two classes of lamps for street lighting, some hanging lamps, and some on brackets, especially adapted for lighting shops. In this group there are twenty lights fed by one machine, driven by a 15-horse power portable engine, made by Messrs. Crossley Brothers; this installation is also under the charge of one man. Near the theatre is a series of lights

THE ELECTRIC LIGHT AT THE FISHERIES EXHIBITION.

THE arrangements for the lighting of the Fisheries Exhibition are upon a most extensive scale, and should the promises of the catalogue be fulfilled, will form one of the most interesting shows of the kind. Most of the well-established systems are amply represented, while on the other hand there is a total absence of unknown names from the list of exhibitors. The feature which distinguishes this show from previous ones is, that instead of the various systems being massed in a large hall, where the effect of the whole was blended into one great glare of light, each will have its own special building, and can be there disposed in the best way to show off its special advantage. The Exhibition is so extensive that this is readily possible, without stinting the space afforded to each, while the great diversity in the forms and dimensions of the buildings renders it easily possible to find suitable opportunities for the display of all sizes and varieties of lights.

The main vestibule is to be illuminated by 500 incandescence lamps supplied by Messrs. Woodhouse and Rawson, and fed by Messrs. Elphinstone and Vincent from two of their dynamos. At the end of the vestibule, where a short flight of steps leads into the British Sea Fisheries Section, will be seen the magnificent exhibit of Messrs. Siemens Brothers to which we have already alluded in a previous article. 1000 Swan lamps will be disposed upon the underside of the pinnacles of a reduced model of the Eddystone lighthouse, 60 feet in height, probably forming the most striking example of electric lighting that has yet been arranged for exhibition purposes. These lamps will be fed from two alternate current generators of large size, separately excited in the usual way. Messrs. Siemens Brothers also provide four arc lamps in the conservatory, each of 2000 candle-power; these will be arranged in parallel circuit instead of in series as has hitherto been usual, the lamps employed being of the hanging pendulum type, and being used without any modification whatever. The range of refreshment rooms to the left of the first gallery will be lighted by twenty-eight Lever arc lamps, fed by two Hopkinson and two Gramme dynamos. The passage leading to the right, past the dressing room of the Prince of Wales' Pavilion, is to be occupied by Mr. Matthiesen, whose lamps have lately been exhibited at the Aquarium, where they were severely handicapped by the insufficient supply of steam. Branching from this passage to the left, the machinery in section will be illuminated by 25 Gilbert lamps, arranged in parallel, and to the right the life-saving appliances, which are to be partly lighted by the Electrical Power and Light Contact Agency by six Werdermann lamps. At the end of the gallery one enters a small building devoted to the Newfoundland fisheries, divided between Newfoundland, the Netherlands, Denmark, and Belgium, and this is to be furnished with sixty Jablochkoff candles, while the latter country will be provided with three Lea and Gerrard lamps respectively. This brings us to the promenade gallery, in which will be found the only striking novelty of the show, viz., fifty Hochhausen lamps supplied by Mr. Edmunds, who further provides 500 incandescence lights in the eastern gallery, parallel Exhibition-road, and on the upper terrace a light tower on the same plan as that in Madison-square, New York, carrying six large lamps of 12,000 candle-power each, driven by a Hochhausen dynamo. We have heard much of the success of these towers in the States, and shall be anxious to see how far they are adapted to our climatic conditions. The aquarium, which bounds the garden at the side nearest Queen's Gate, is to be lighted by 1000 incandescents lamps driven by a single Ferranti-Thompson dynamo, while the adjoining building will be furnished with eight lamps in the same firm. The Gilchrist Company, in addition to the installations we have already mentioned will have twelve lamps in the Spanish section, and 400 Crookes' lamps in the Italian section, which are included in the contracts for the Eastern Pacific. This almost concludes the list, and we have only to note twelve Gerard lamps in the Russian Section, seven arc lamps in the Fish Market, and two Hawkes lamps at the entrance to complete the catalogue, as far as it is at present determined. Messrs. Goddard and Gibbs are to have twelve stations for the demonstration of their method of distribution by secondary generators, but at present their situation and extent are not decided. There has been a great deal of bidding among the exhibitors to see what their competitors would do, with the result that the whole installation is very beleaguered, and cannot be expected to be in operation before the commencement of June. At present Messrs. Siemens Brothers are the only firm that are ready to commence lighting

Engineering April 1883.

ELECTRIC LIGHTING NOTES.

DURING the recent six days' thunderbolt on board the steamboat Rainbow, now lying off the Eisteddfod, Swansea, and moored to the Victoria Dock, Cardiff, the Rainbow is attached to the Royal Reserve, and the performances were given in aid of a charitable fund. There were 28 Swan lamps, of nominal 16-candle power, but each lamp gave in practice more light. They were supplied with current by a primary battery of large cells of the Kinnersley pattern, which work with 53 volts of electromotive force at 1.8 volts per cell. Each cell has approximately a short circuit. The cells were joined up in series; the total electromotive force being 53 volts, and the current 21 amperes. By means of the switch the current could be divided amongst the different lamps so as to produce light or darkness in each of the tents of the stage. The light was maintained for ten hours.

THE Egerton woollen mills at Ucclfarr, in the Pendleton, have been lighted by 16 Brush lights, fed by the irrigation canals, and the installation may be regarded as the first step towards the utilisation of water power in these three canals, which would create some 1000 horse-power. The looms, carders, and other machinery are well lighted, and the native weavers can read the colours of their cloths with ease, distinguishing without difficulty light is 10 pence, or 7½ per month, and a saving is effected on insurances. The installation was made by the Eastern Electric Light and Power Company. While upon this subject we may also mention that the Brush light is found very useful in the Kimberley diamond mines, South Africa, after dark, since it enables the colours of the stones, when a diamond is found, and there is a request to light the entire mines by it, but owing to the cost of coal this would be an expensive undertaking.

THE management of the Savoy Theatre having determined to abolish gas-lighting altogether in the entrances, corridors, and offices, Messrs. Spagnoletti and Son are supplying some tasteful fittings for the Swan lamps, which Messrs. Siemens Brothers are erecting in placing them. The corridors are to be three parts lighted from walls with 8 in. carved reflectors, the lamps depending therefrom only a few inches below the ceiling. The electrician for the royal rooms is a gentleman connection between the banks, from which the lamps hang. While referring to Messrs. Siemens, Faraday and Swan, we may mention their display of new designs in electroliers, &c., in conjunction with the accumulators of the Electrical Power Storage Company at the Manchester Exhibition. Reflecting pendants made for the workings of the Swan and Co. lustrous candle for the workings for theatres, saloon fittings for ships, and an ingenious double swivel bracket for bedrooms, also form part of their exhibit.

Part of the town of Nantua (Ain), in France, has been lighted with an semi-incandescence and discharge lamps by M. Emile Reynier. The generator is a Siemens continuous current shunt wound dynamo of the type S D A, weighing 130 lbs., and absorbing one horse-power. It is driven by a hydraulic motor. The current is led to charge thirty-six Reynier accumulators joined in tension. These accumulators are of two distinct sorts, eighteen are of copper and eighteen are of zinc. The first consists of a plate of lead peroxidised as positive pole, and a plate of lead coppered as negative pole. They have an electromotive force of 1.93 volts, and weigh about 25 kilogrammes (55 lb.) per cell. The zinc accumulators consist of a peroxidised lead plate as before and a negative plate of lead coated with zinc. The weight of a cell is 23 kilogrammes (50 lb.), and the electromotive force 2.3 volts. These thirty-six accumulators are in tension, and represent a total electromotive force of 71 volts and an internal resistance of 0.18 ohm. They supply 12 Edison lamps of 16 candles, which work with 53 volts of electromotive force. The lamps are joined in parallel or derived circuits. The accumulators also feed four Regnier semi-incandescence lamps, which resemble those of Verdermann and Jaed, and work in multiple arc lamps. There are three of 16 candles each, and one of 32 candles. The lamps require 53 volts, a resistance is inserted in the general circuit and regulated by a key which increases or lessens it in proportion to the discharge required for maintaining the light. The four semi-incandescence lamps have also one derived circuit, and to prevent the extinction of the lamps during the rest 36 Regnier cells are used, a secondary battery to each, these being joined in tension in such a way that their electromotive force is opposed to that of the first current. When the latter fails no current passes through the batteries, but when a lamp through accident ceases to act, the secondary battery in the batteries of the other series of lamps keep them lighted and are fed by the current. A similar plan has been patented in this country. M. Reynier's installation at Nantua is peculiarly interesting from the fact that three sources of lamp are employed in it and are fed by the same source. The accumulators of copper and zinc are also novelties which have stood the test of trial, and the utilisation of waste water power is another feature in the work which adds to its merit.

ELECTRIC LIGHTING AT THE BRÜNN THEATRE.

SOME time since (see ENGINEERING, vol. xxxiii, pages 18 and 204) we described the lighting of the Savoy Theatre and considered at some length the advantages gained by the use of the electric light in theatres. Little has happened since that date to modify the opinions then expressed, and later installations have tended to show how numerous the advantages are, both as regards the quantity and quality of the light, and the improvements in ventilation. Below is given a very successful installation of this class recently fitted up at one of the new theatres in Brünn. The particulars and drawings of this installation are taken from our esteemed contemporary *Die Elektrizität* (*Zeitschrift für Elektrotechnik*, Vienna), which recently published a lecture read by Mr. Ludwig Fischer, of Brünn, upon the electric installation at the Sarony and the Brünn theatres. Since we have already published a plan of the former and a diagram of its installation we do so now in Figs. 1 to 4, on page 350, and say, that the plan of the Sarony is Fig. 1, and that of the Brünn Theatre, Fig. 4, are drawn to the same scale, which at once shows the great difference in the dimensions of the two buildings, Brünn, the capital of Moravia, is one of the most important manufacturing towns in Austria; its 90,000 inhabitants are for the most part engaged in cloth and woollen manufacture. The theatre, which accommodates 1200 persons, was originally intended for 1000, but after the experience of the fire at the *Ring* Theatre in Vienna, the passages were considerably widened, and four instead of two side exits as originally proposed, were provided. The enlargement of the means of the internal ways necessarily curtailed the seats in the auditorium. The theatre is externally imposing and internally provided with all modern improvements, and is very tastefully decorated in white and gold, with a profusion of gold. Massive walls, varying from 2·7m. to 4·6. 6in., in thickness, with iron girders and tie accessories from the rest of the building, while iron curtains divide the principal stage both from the auditorium and from the large room at the back of it. No gas is used for any purpose in the Brünn Theatre, electric illumination having been adopted long previous to the completion of the building. The contract was carried out conjointly by Messrs. Schuckert, Nürn, and Co., of Vienna, and the Brünn Engineering Works.

The engine and boiler houses, illustrated in Figs. 5 and 6, contain three semi-portable *locomobile Dolzwitz*, a pair of horizontal compound engines coupled to one fly-wheel, driving by means of ropes, the countershaft below. The boilers consist of three cylindrical flue boilers, 5m. long by 2·1. 8·5in. in diameter, fitted on to a vertical tubular boiler 6·6. 0·5in., and 2·7. 0·5in. in diameter, provided with 69 tubes 2·1in. in diameter. The total heating surface of each boiler is 500 square feet, and two only are required to supply the necessary steam, leaving one always in reserve. The grate area is 19·6 square feet, which appears to be the proportion of grate area to heating surface both as 1:25. The feed is heated by waste steam to about 100·5deg. Fahr. by the exhaust steam in a feed-water heater of 170 square feet of heating surface. The chimney has a sectional area of 19·6., and is 40m. high. A steam jet is provided, which is put in operation each time after firing.

The motor is a double-cylinder coupled high-pressure Corliss engine, fitted with 150 h.p. cylinders, 311 in. stroke, working at 75 revolutions per minute, cranks being set at right angles. The flywheel, grooved to receive the seven large ropes, is 17·5 in diameter, 1·5 in. wide, and weighs 12 tons. Exposed to steam about six times, that is cutting off as soon as it gets a commencement, about 28.3 lb., each cylinder indicates 65 horse-power; should any repairs be necessary to one cylinder, the full power can easily be resumed, and all the work is done with one cylinder only. The main rope driving pulley on the engine shaft is 4·6 in. diameter, and as the speed is 300 revolutions per minute, the rope's speed is said to be 700 feet per minute. The seven dynamo machines are driven by seven ropes of cotton belting. The Edison machines are provided for supply the inverted incandescent lamps, while the Siemens machines provides the current for five flaming arc lamps of 1000-candle power each, placed outside the theatre; another small dynamo is reserved for special effects by means of arc lamps on the stage; these two machines require respectively five and two horse power. The Edison dynamos are of the K pattern capable of supplying each 200 incandescence lamps of 16-candle power, but since the four collectively have seven times 200 lamps to maintain at full power they are usually not worked to their total capacity; a spare dynamo is not provided, and in case of a breakdown the three machines must suffice to do the work. The resistance of the armatures in these dynamos are 0·0625 ohms, that of the magnets 12.18 ohms, strength of current 133 amperes and the tension between 102 volts; each machine consumes 20 horse-power when at full work. Fig. 7 represents the arrangement of joining the terminals of the four machines, and the current of each machine passes through a switch, after which the four circuits are joined into one main circuit. The arrangement is adopted for the exciting circuit shown in dotted lines. The united current passes through one of two Schuckert ampère meters Fig. 8, one of one of Schuckert's thinometer, to the theatre, a distance of about 120 yards. This cable is placed in a trench 3 ft. 3 in. deep and at distances of about 20 ft.; separate cables, as illustrated in ENGINEERING, vol. xxxiii., page 606, Fig. 7, are provided.

The installation inside the theatre consists of 1400 Edison incandescence lamps of 16-candle power each, of these the cable enters the building as at once divided into two lines, to one of which all these lamps are joined which illuminate the entrance hall, passages, and which requisite are also illuminated during the whole evening; the number of these lamps is 300. The second and no cable changes alternately, the lamps in the auditorium and on the stage. There are 800 lamps in the former and one the latter, while a few are also supplied from the engine-room, making a total of 1292 incandescents in daily use for Edison dynamos. For driving a small Siemens dynamo, supplying the current for small Edison lamps of 8-candle power each, and in this engine-room, arranged in the basement of the theatre, leaves the engine-room, and then grows the gas engine also serves to drive the ventilating fans. Fig. 8 shows the switch for the two exciting circuits, Fig. 9 shows the switch for the two cables, the short bars in, being of iron, the current overheating placed literally in the Brünn installations, are being divided for 4 light groups each. The switch-table rises vertically from the basement, having branches on every floor, each one of which is provided with a safety switch, B, and an ordinary plug switch, A, Fig. 10. The stage lamps are divided into three groups, one set while, one set red, and one green, for different stage effects, the colours being obtained more than one of these lamps groups are in operation at the same time, the total number of lights being somewhat over 900 lamps. The regulating switches shown in Figs. 10 and 11, are also well complicated, as in the case of the various experiments in theatre like that of Brünn, which have requirements of the kind, it is necessary to have all the lights under control, and yet to be able to regulate, in any moment, any one or more groups, or any individual switches, with great rapidity, which can be flowers, bells, and a number of distances; the switches are so, that any part of the circuit may be cut out, and the lamps in the various circuits, so that different groups can be regulated in the lamps currents. The switches B and C, Fig. 10, are ordinary switches, and A and D, Fig. 11, are switches for the regulator is placed on the stage, Fig. 4.

All the lamps in the auditorium are provided with ground opal glass globes, which soften the light considerably, and the terrace of the contract upon by the architect; this arrangement was not successful, the effects with the shaded to cover the whole stage. All the lamps on the full light would be too hot for full light, and it is said to be 700 hours, and for temporary illumination 50 oil lanterns are provided.

Particulars as to cost of lighting this theatre are not given, but the installation has so far proved very satisfactory, and the terms of the contract with the Brünn Engineering Works, and the municipal authorities of Brünn, and the contractors bearing on the point of cost, are as follows: The municipality provide the complete installation free of charge, also for a monthly rent of 140fl. maintain the same for twenty years, after which time it becomes the property of the town. According to particulars in the contract, 700fl. are supposed to go towards payment of interest and amortisation, while the other 700fl. pay for maintenance. In case of failure the conditions named rather lenient for the contractors; for the extinction of ten lamps or more, ten shillings, and in addition the contractors provide light by means of the oil lamps during such derangement of the electric lighting.

All copper leads in the Brünn Theatre are protected by silk, as layers of lace, soaked in insulating solution and they have so far given good results. Since the Savoy Theatre and the new Opera in Rome have successfully adopted electric illumination, quite a number of other theatres have followed this good example. The Théâtre Variétés in Paris, with 1200 lamps; the Eden Theatre, Monte Carlo, and Sonzogno Lamps, the new theatre at Munich, the Italian Opera in Paris, and a little theatre in Havanna, are all provided with Edison's system.

of their goods, including fish tanks and slabs suitable for fish-curing yards, fishermen's houses, coopers' or bait shops, piers, &c. On another occasion we may take somewhat more prominent notice of the generally commendable case, and the extent to which the material is now being used.

Coming next to Class VIII., which is very comprehensive, though not fully illustrated, we notice a model of Aberdeen Harbour, and a plan of the same, furnished by Mr. William Smith, harbour engineer; Arbroath and other models of harbours are also exhibited, one of which is a model of a proposed new harbour for Tynemouth, from designs by Messrs. Thomas Meik and Sons, civil engineers, Edinburgh. Every item of the design is well fitted to assist in making a most secure fishery harbour of very great extent, and at comparatively small cost. Dysard—by the scheme will doubtless be carried out. Another exhibit of a similar kind is a model of Buckie Harbour, and photographs of the same, sent by Lady Gordon Cathcart. Several plans and models of fishermen's dwellings are likewise exhibited; and Mr. Meehan, city architect, Edinburgh, shows a model of a proposed wholesale fish market, in which there are embodied some excellent structural features. Messrs. Low and Duff, of Dundee, show a sample of their gun for firing lines from shipwrecked or stranded vessels to shore, a very ingenious piece of apparatus which has already been described in our columns. As in most other public exhibitions, there are here several examples of the proverbial "fly in amber," one of which is nothing less than a "patent gas governor for equalising the pressure and increasing the illuminating power of coal and other gas." Why such a piece of apparatus should get in amongst collections of fishing garments, models of fishing boats, &c., is a difficult to understand.

As was naturally to be expected, the question of pollution of rivers is prominently illustrated in the Fisheries Exhibition. In Class X. there are three systems of treating town sewage and manufacturing waste very fully illustrated by models, specimens, &c. These are the A. B. C. system, as pursued at Aylesbury, the one pursued at the Hawick Sewage Purifications Works, and that adopted by the paper-making firms on the North Esk, Midlothian. The first has been so often described that we need not enlarge upon it; but the others are still possessed of much a great degree of novelty and industrial interest that we shall probably take an early opportunity of dealing with them at some length.

We had almost omitted to take notice of the exhibits in Class IV., which comprises piers, (new-

ings, models, &c., of fish passes, stairs, and ladders for enabling salmon and other migratory fish to surmount the natural and artificial barriers that obstruct their descent to the spawning grounds in the rivers of this and other countries. There are in this class some nine or ten exhibitors—Scotch, English, Canadian, and Norwegian. Two of the exhibits are models executed in Stuart's patent granolithic composition of salmon passes—one at Morphie, on the North Esk; Forfarshire, and the other at Dunnaton Mills, on the Tarth, Perthshire. The actual passes are in length, respectively, about 70 ft. and 250 ft.

Next week we propose to mention some of the exhibits on account of which medals, money prizes, and diplomas have been or may yet be awarded, and at the same time we may possibly refer further to the Exhibition.

THE EDISON SYSTEM OF ELECTRIC ILLUMINATION.

In our last article on the Edison system* we described the form and process of manufacture of Mr. Edison's incandescence lamps, as well as some of the fittings supplied with them, several of which possess points of special interest, and display much ingenuity. On the present occasion we shall go on to describe the conductors adopted under the Edison system for what the French call the *canalisation* of the current, and by which electricity is distributed over a district to be lighted from a central station; we shall then refer to some of the switches and other details connected with the distribution, and lastly to the apparatus devised by Mr. Edison for regulating the strength of the current as the work it is required to do, and the instruments by which the extent to which the current is utilised by subscribers or lost through defective insulation is measured and recorded.

The conductors may be grouped into three classes, viz. (1) the principal and submains which carry the great bulk of the working current beneath the streets, and to the subways; (2) the conducting cables which are employed for the comparatively short house-service leads, supplying the currents to such numbers of lamps as rather would require the conductors of the first group; and (3) the single insulated wires of small sectional diameters by which the groups of lamps are placed in circuit with the service conductors and their branches. Those of the first class, or electric mains, alone require special notice, the two other classes, differing in no material respect from the electric light cables and wires used under other systems.

The mains are, however, of peculiar and interesting construction. The conducting portion consists of two solid copper rods of segmental cross section, clearly shown in Fig. 1 on the opposite page, which represents a cross section of these different-sized three conductors, suitable respectively for large mains or for branch circuits, or for the mains of smaller installations; the two segmental bars are protected from injury and from moisture by being passed through the middle of a wrought-iron pipe, and are held in position in the final place by diaphragms punched out of stout millboard, which is threaded on to the bars at intervals along the length of the tube; and the whole of the conducting systems are filled with a bituminous insulating compound which performs the threefold duty of keeping the conductors within the limits of the tube throughout their length, of serving as an insulating material protecting the conductors from damp, and of so completely filling the tube that the latter, with its conductors in place, can be bent to any desired angle without any distortion of the sectional cross figure, or displacement of its contents. At both the Paris Exhibition of Electricity and the Electrical Exhibition at the Crystal Palace, specimens of these conductors in various sizes, some seven years old, and others a couple of years old, were exhibited, and any one rode of such a length and necessarily of such a constructions, would naturally follow that unless some provisions were made to allow for contraction or length without distorting the mains, they would to a short distance themselves, or at least would soon be injurious to both conductivity and insulation. The arrangement for meeting this difficulty is shown in Fig. 1, which is an illustration of one of the main junction boxes with its cover removed. This consists of a box of cast iron (A) with double walls, through the side of which (B) pass the ends of two pieces of conductors X Y, one of which is to be joined on to one section of the mains, and the other to the next section. Or Labeled strips of metal, by way of example, being of equal sectional area to that of the conductors X Y, on account of its form, to that of the conductors X Y, on account of its form, are employed for closing or opening under the elongation or shortening of the straight conductors. The illustration also shows the method of connecting a lamp circuit in parallel or with the main circuit; the conductor C being connected to the loop A by the copper strip D, while E is a notable connection with B by the lead strip C. Every branch circuit throughout the system is provided with a protected against any sudden increase in the strength of the current by being provided with a safety guard consisting of a short length of lead wire, through

* See ENGINEERING, page 365 *ante*.

which the whole of the current passing into a branch is broken and breaking of the circuit. Fig. 10 is a view of the back of one of Mr. Edison's switches, showing the internal arrangements. This switch is so designed that by turning the handle M H through a portion of a revolution, the three contact springs, shown in dotted lines in Fig. 9, and in position in Fig. 8 on page 359 of our issue for March 30th, are simultaneously thrown out of contact with the screws I, and D. The current enters by the screw I, when the switch is "on," passes through D, C, B, A, E, H, F, and G to the other screw I, and the circuit is completed. When the switch is suddenly reversed by the attachment of a cane handle, a strong spring is released, which instantly throws the three springs into the position shown in the illustration. The switch recently used at the Savoy Theatre, and referred to in a recent issue, is of this description, but is somewhat smaller and more compact than the one illustrated.

PATENT LAW REFORM AND SIR LUBBOCK'S BILL.

ONE of the [illegible] Parliament [illegible] the memorial is the fifth, which, like the rest, is simply three words, "Dissolution in fact," and a short general notice, and was signed by [illegible] fill do not represent as much [illegible] [illegible] years, viz., 77l. 10s., that amount less than half the fees now payable on [illegible] only fourteen. The fees now payable on [illegible] several payments is 150l., but this amount [illegible] for personal protection—77l. 10s.—and [illegible] comes somewhat too short, regard being had [illegible] assistance to be referred to, for [illegible] ment, i.e., 50l., the certificate of renewal [illegible] fee of patent in the certificate of renewal [illegible] Lord Wise to the [illegible] Society last January. THE ELECTRIC LIGHTING OF NOTTINGHAM.

The Telegraph Construction and Maintenance Company is the latest candidate for admission to the roster of the electric lighting fraternity. With this object it is promoting a Bill in Parliament to enable it to keep the scope of its operations, and in the meantime it has given in a tender to the Corporation of Nottingham to supply them with plant, consisting of distributing mains, generators, engines, boilers, and buildings for an installation of 60,000 incandescence lamps. The well-known scientific skill and business ability of the directorate of the company, as evidenced by their great success in a manufacture beset with difficulties, will command for their proposals an amount of respect that has not been accorded to many companies who have no previous history to point to. It may be assumed that this offer represents a genuine business project, designed to give satisfaction to the purchasers, and a fair profit to the manufacturers, and does not, in any sense, partake of the nature of an advertisement to be afterwards used in the manipulation of the share market. In these terms one of the most substantial pieces of evidence that has yet appeared, of what is the cost of introducing the electric light on a tolerably large scale, and though it does not greatly differ from many estimates already published, yet it carries far greater assurance from the fact that its authors are ready to enter into a binding contract to carry it out.

As is well known, the Telegraph Construction and Maintenance Company have adopted the Gordon generator for the lighting of their extensive premises, and it is this type of machine that they propose to employ in town lighting. On page 507 of our last volume will be found an illustration and a full description of the generator at the Greenwich works. The leading feature is that the field magnets are mounted upon the periphery of a large wheel, which revolves between two sets of stationary armatures coils. Thus the current is received from the armature without any rubbing contacts, and the machines can be grouped in any desired order, and arranged to feed any reasonable number of circuits. The machines already at work has been proved to have a high efficiency, while the slow speed at which it is driven avoids much difficulty in the matter of lubrication, and affects a saving in wear and tear. Unfortunately, however, it produces alternate currents, and this we hold to be a great objection to its use for town purposes. The amount of electricity that will be expended in the production of power, when it is laid on to our houses, will rival that annually used for, and up to the present no motor success. The introduction of domestic labour-saving machines has been almost prevented by the necessity of driving them by hand, but if a means of working them by power were provided, without any danger or trouble from steam, gas, or batteries, their number would increase by bounds, and the sewing or the washing machine, as universal as the domestic motor would become as universal as the

The installations at Nottingham is intended to furnish a continuous supply of a current of electricity, sufficient for the maintenance of 60,000 8-candle lamps of 20 candle-power each, for sixteen hours out of the twenty-four, and of one-third of that number during the remaining eight hours, to all the houses, warehouses, shops, factories, street lamps, &c., in a specified area. Five Gordon dynamos are to be provided, four to work and one to spare, and one each to be driven by a pair of compound condensing tandem engines of the vertical inverted cylinder type, capable of developing 1700 indicated horse-power at 150 revolutions per minute. There will be six direct current machines to excite the magnets of the large generators, and these will be driven by independent engines, whose speed will be regulated so as to maintain a field of such an intensity that there will be a constant difference of potential between the mains, whatever may be the number of lamps in action. Steam will be provided at a pressure of 120 lb. to the square inch by 38 boilers, fitted with Galloway tubes, and each capable of developing about 220 indicated horse-power, so that 30 of them may be at work and eight idle. Mechanical stokers are to be fitted to the boilers, and the coal is to be delivered into them from an elevated store capable of holding 1000 tons. The valves are to be of copper rods of such section that the current shall not exceed 1750 ampères per square inch; and are to be arranged in eight double circuits. These double circuits are a novel feature; each mains will have its lamps divided into groups supplied from two independent sources by parallel mains; and thus the chance of its being left in darkness will be greatly diminished. At the same time additional compilation will be introduced, for there will be four leads in each building instead of two, and these cannot be coupled together in parallel are as would be the case if the circuits were direct.

When the installation is complete the contractors are to run it for thirty days at its full capacity, or as near that as the demands of the consumers will allow, and if it prove successful it is to be then handed over to the corporation, and the last instalment of the purchase money is to be paid. The contract price is to be 250,000*l.* or 3*l.* 12*s.* 8*d.* a lamp, a lower amount than we remember to have seen named before, but it must be remembered that the plant is on a much larger scale than that of any previous project, and that the price does not include the price of the site, or wires or lamps on the consumers' premises.

Following the specification there comes an appendix, giving the estimated working cost of 60,000 lamps. The information is given for the guidance and convenience of the corporation, and it is believed by the authors that the figures are correct, but they are not in any way guaranteed.

Upon the assumption that the lamps will burn 2500 hours per annum, the annual charges are estimated thus:

	£
Depreciation and repairs of plant ...	10,000
Coal (21⅓ per indicated horse-power at 5*s.* per ton)	9,625
Oil, waste, &c.	500
Labour and superintendence	5,375
Rates	500
Other rates and taxes	500
Office expenses	600
Renewal of Swan lamps at 2*s.* per stand lamp hours	15,000
Interest at 5 per cent. on 220,000*l.* ...	11,000
Total	53,700

The cost of 60,000 gas jets, each burning five cubic feet per hour, with gas at 2*s.* 6*d.* per thousand feet, would be 93,750*l.*

Thus the cost of an electric light is shown to be 18·6*s.* per annum, as against 31·25*s.* for a gas jet.

Moreover, the figures, excepting the lamp renewals, seem to be fairly estimated; it is not easy to calculate the repairs and depreciations of such a plant, but if the possibility of its being superseded by some other means of generation be overlooked, 4½ per cent does not seem to be an excessively small estimate, especially when it is remembered how much of the capital is sunk in buildings, foundations, and mains. The coal and labour are also liberally allowed for, but the item of 2*s.* as the cost of Swan lamps per thousand hours is a surprise. It either involves a much greater endurance than the 1200 or 1500 hours usually counted upon, or else a reduction of 60 per cent. upon the present price. As matters now stand it must be raised to 3*s.* 3*d.*, and this will add 9270*l.* to the annual charges, and bring the cost per lamp to 21·75*s.*

But however correct its circumstances may be, the premises upon which they are founded are open to fallacious, consequently the results are totally misleading, and if the Corporation of Nottingham accept them they will be greatly disappointed. If a lamp is to work 2500 hours per annum it must be in operation on an average for nearly seven hours per day all the year round, or if Sunday be omitted for eight hours per day. Now let us see what would actually be the case. At half-past four on a winter afternoon the installation would be working at its full capacity, and 60,000 lamps would be drawing their supply of current. About five o'clock there would be a decrease in the current supplied to banks and offices, while at half-past seven woman and child in the textile factories must cease work, and accordingly the current required by the mills would be greatly diminished. At six, again, the warehouses would close, at eight the shops, at eleven the public-houses and places of amusements, and by midnight the demand would be restricted to the street lamps and an occasional light kept burning as security against burglars. Thus within about an hour of the evening lighting being fairly commenced the restriction of the demand sets in, and in four hours a great part of the original 60,000 lights will be extinguished. This opposite says, however, that "if instead of each lamp (gas or electric) burning 2500 hours per annum, one or more lamps alternately make up the 2500 hours, the result will not be altered, the electricity and gas being alike supplied by meter." Let us therefore see under what circumstances one set of lamps may be expected to replace another set that has been put out. This will occur in two cases at least; firstly, of course, a demand will spring up at the places of amusement between seven and eight, but this does not amount to much in provincial towns; and, secondly, the domestic lighting will be greater as people return home for the evening. But neither of these instances will supply sufficient ground for the reduction of light in business premises; in the houses of the wealthy the return of the proprietor produces no extra illumination, while it is not to be expected that the mill hands, who seldom use gas, will go to the expense of introducing the electric light into houses hold on a weekly tenancy.

We will now summarise the lighting for a December day (not being a Sunday) at

	Hours
Banks	4
Offices	11
Mills and workshops, morning and evening	4
Warehouses	4
Shops	5
Theatres	4
Hotels	4
Streets	16

At Midsummer this list would dwindle to

	Hours
Banks	4
Offices	4
Warehouses	4
Streets	16

It is very difficult, of course, to strike the average times per lamp, but seeing that offices, mills, warehouses, and shops will take the greater part of the supply, and that these are all closed on a Sunday, it would seem that 1225 instead of 2500 hours per lamp would be an exceedingly liberal estimate.

Considering the value of the annual charges upon this basis, we arrive at a very different result. The depreciation and repairs remain the same, that is 10,000*l.*; the coal account would be halved, the petty stores reduced to 250*l.* 000*l.*, the labour and supervision would be practically the same for the machinery must always be running, but we will reduce it to 4500*l.*; rent, rates, and taxes would be halved, while the rent for the use of lamps, at 3*s.* 3*d.* per 1000 hours, would be 12,187*l.* The interest would likewise remain constant at 11,000*l.*, hence the total would be 46,826*l.*, or 15·6*s.* per lamp as against 18·62*s.* per gas jet for the same time; that is gas and electricity would cost practically the same if an average use of 1250 hours per lamp could be secured.

That the period will not be exceeded it, we think, beyond contradiction, and it depends greatly upon local circumstances whether it will be exceeded. Street lamps burn 4000 hours a year, and no doubt in the specified district to the new undertaking, but unfortunately they only occur about once in fifty yards. Manufactories working all night, as do some of the total cost for a winter 2000 hours' consumption, while dwellings are probably illuminated for 1000 hours. This is the across side of the estimate, and upon the other may be placed theatres, &c., 1200 hours, shops 900 hours, warehouses and offices, and places under the Factories Act, 300 hours, and banks 100 hours. It will be for the Corporation of Nottingham to decide what the resultant average will be; the presence in the town of a manufacture which, to a certain extent, is continued through the night, will be an item in the favour of the electric light, and if they can induce a sufficient number of millowners to embrace their scheme they may carry it out without loss, after it has had time to establish itself in the town, but this must take some years at least, during which an increased charge must be made over the present price of gas.

"ELECTRIC LIGHTING NOTES."

THE Canadian Telegram belonging to the Dublin Company of New Zealand, is to be fitted throughout with the incandescent light on the Swan system. This makes the fifth vessel belonging to the company now partially lighted; of the four previously fitted two are on the Swan system, two on the Siemens system.

We understand that the new pensions recently fitted up for the officers of the *Irish Times* in Westmoreland-street, Dublin, are to be lighted throughout on the incandescence system of electric lighting. The installation is to be executed by Messrs. Siemens, and will consist of 150 Swan lamps of 20 candle-power each worked by an alternate current machine and an exciter. The lamps will be arranged in four circuits, so that one or more circuits may be cut off at pleasure, and each lamp will be provided with a switch for putting on or off the current as occasion may require. Fusible plugs are also to be inserted where necessary. The motive power will be supplied by a 12 horse-power (nominal) Crossley gas engine, suitable connections for which are to be made with the water and gas services for the purpose of overcoming the unsatisfactory inclination to gas engines. The installation has been ordered through, and will be carried out under the superintendence of Mr. J. Angelo Falke, Memb. Soc. C. E. and of Edison, of Dublin.

The numerous confident assertions that the Jablochkoff candle, though invaluable as a pioneer, can have no chance of survival in the struggle of the systems, appears to be fully contradicted by its intended extensive adoption for subterranean street lighting. Since days of since it was announced that a large part of the parish of Marylebone is to be lighted by the Jablochkoff Electric Light and Power Company. The district selected is, as is doubtless the parallelogram bounded by the following streets; Church-street, Edgware-road, Harrow-road, Bath, Orchard-street, and Baker-street, and Park-road, Regent's Park. It is estimated that 200 lights will be required for this area. Many recently-laid water and gas mains forming the Strand Union, namely, St. Anne's Soho, St. Giles-in-the-Fields, St. Paul's Covent Garden, the Precincts of the Savoy, and Liberty of the Rolls, and St. Mary-le-Strand districts, have been undertaken to supply the parishes with light at a moderate rate price, and many old conditions accept a seven years' contract; becoming, in fact, the servants instead of the controllers of the district. The company, however, reserve the right of supplying light either are or incandescence (the latter or other systems) to private consumers, and with the object sufficiently large main conductors will be laid in the streets. It will be seen that it is a hardship by other associations that a company with such little less hitherto been heard, should have control from districts they considered their own, and from which they have spent comparatively large sums in preliminary work. But we think that the public will be congratulated on the prospect of having an important district thus lighted by a new and well-tried system, and not by the old control of the authorities. Another point in the expenditure contemplated by the Jablochkoff Company stands half a million sterling, including the necessary lighting over a large area of the City, the Strand, and Fleet-street not yet settled.

At the several general ordinary meeting of the Electric Lighting, Contract, and Maintenance Company held on Wednesday last, Mr. Crompton stood up to the undertaking and returns the capital—less some small amount for expenses incurred—to the shareholders. The company looks forward to reconstitution at some future day, but the shareholders were convinced the time for them had not yet arrived. We trust that the shareholders of such other companies as may be compelled sooner or later to execute the happy despatch, may find themselves in the position of those forming this company.

The Hammond Electric Light and Power Supply Company, the object of the Brush electric, appears to be in the most flourishing condition of any of the family.

At the general meeting, held last Tuesday, the accounts presented by the directors showed the sum of 12,252*l.* 19*s.* 8*d.* as profit for the year 1880, and this sum it was proposed to apportion as follows: 1000*l.* in payment of a 5 per cent. dividend; 5000*l.* to be written off the goodwill and concession account; 5000*l.* to be placed to the reserve fund; and 1025*l.* 5*s.* to be carried forward. The liabilities of the company consist of paid-up share capital 80,000*l.*, creditors 8230*l.*, and a sum of 14,857*l.* to the credit of the Brush Company. The assets are goodwill, concessions, and patents, 41,097*l.*; debtors, 7699*l.*; plant, machinery, stock, and furniture, 29,055*l.*; rejected new stock on hand to be returned to the Brush Company, 8231*l.*; electrical college and lamp factory, 1656*l.*; cash, 22,966*l.*; shares in Ferranti and Co., 375*l.*; shares in sub-companies, 32,102*l.*; and preliminary expenses, 1000*l.* The profit and loss account does not give much clue to the extent of the company's operations, because it deals only with the profits on contracts and on material sold, and does not specify the gross value of the plant disposed of. Thus, during the year 1880, the account sale up to 12,000*l.*, leaving a balance from sales to concessionaires of 2165*l.* The profit on contracts is 5086*l.* from profit on completed installations and tracts and on materials sold, and the remainder 3191*l.* from discount, interest, and transfer fees. On the other side trade expenses amount to 6265*l.*, directors' fees to 1000*l.*, salaries and laboratory expenses to 1201*l.*, depreciation to 2166*l.*, and other expenses to 450*l.*, the balance of net profit being 12,252*l.* It will be noticed that this is less than the balance of sales from concessions account, and that consequently no profits has been gained by the sale of machinery or light. It is, however, hardly to be expected that an intermediate company should make a profit the first year of its existence, especially when it is remembered how many unfavorable circumstances have been arrayed against it. The shareholders will not quarrel with the dividend on account of the source from which it is derived, though it is certain, since that some of them are anxious to know upon what basis the value of the shares in the subscription is computed, seeing that those figure as their largest asset. From the accounts and the report we hear how greatly the relations between the Hammond and the Brush Companies have improved. The directors, acting under the advice of counsel, have determined to return to the purchasers of the Brush lamps in Manchester, Sheffield, Warwickshire, and Worcestershire, a considerable portion of the consideration money on account of the Edison difficulty, and are asking the Brush Company to make good the amount. We believe that this falling on the latter company they will bring a further action against the parent company for breach of contract in the supply of machines, and for absolute failure to supply a Brush dynamo machine suitable for incandescent lighting. If others of the subsidiary companies should follow this example the Brush directors will come to regard their offspring with the pride and satisfaction which they evinced some twelve months ago. The Hammond Company has acquired the sole agency for the Ferranti alternate-current machine, and has further bought, on reasonable terms, the Wright and Mackie manufacturing patents, by which the production of incandescence lamps is much cheapened.

AGENTS FOR "ENGINEERING."

BELGIUM: F. Dalby, 15, Rue du Parchemin, Brussels.
CANADA: Dawson Brothers, 25 and 26, Great Saint James-street, Montreal.
CHINA: Kelly and Walsh, Hong Kong.
DENMARK: John Menzies and Co., 12, Hanover-street, Edinburgh, and 2, Hanover-square, London, W.
FRANCE: Boyer, 74, Rue Turenne, 13, Boulevard St. Martin, Paris.
GLASGOW: William Love.
GREECE: Athens Office.
HOLLAND: P. A. Der Ouden.
INDIA: Thacker, Spink, Calcutta.
MANCHESTER: John Heywood, 143, Deansgate.
NORWAY: Birkland and Dege.
PORTUGAL: Bertrand Irmãos, 73, Rua Augusta, Lisbon.
RUSSIA: Ricker, St. Petersburg and Moscow.
SPAIN: Bailly-Baillière, 11, Plaza del Principe Alfonso, Madrid.
SWEDEN: Samson and Wallin, Stockholm.

Advertisements cannot be received for insertion in the current week later than 5 P.M. on Thursday. The charge for advertisements is twelve shillings for the first line or under, and eight shillings for each additional line. The line averages seven words. Terms for displayed advertisements can be had on application, otherwise their insertion cannot be guaranteed. Terms for displayed advertisements on the wrapper and on the inside pages are considerably higher.

The price of ENGINEERING to annual subscribers in the United Kingdom remaining stable for post it 1*l.* 8*s.* 3*d.* per annum, the following are the rates to which the price is subject, in the case it is 2*l.* 2*s.* 6*d.*, the subscription being payable in advance.

TO FOREIGN COUNTRIES.

The rates for subscriptions to ENGINEERING, when abroad are: 1*l.* 12*s.* 6*d.* to all the following countries, viz.: Africa, Australia, Austria, Belgium, Brazil, Canada, Chili, China, Denmark, Egypt, Europe, Germany, Gibraltar, Greece, Italy, Japan, Java, Luxemburg, Malta, Mediterranean Islands, Mexico, Natal, Netherlands, Norway, Portugal (including Madeira and Azores), Russia, Spain, Sweden, Switzerland, Turkey, United States of America, Australia, and New Zealand.

2*l.* 4*s.* 6*d.* For all other countries, including Cochin-China, Japan, and the Hawaiian Islands (Sandwich Islands).

All accounts are payable to the publisher, Mr. Charles Hamilton, 35, Bedford-street, Strand, London, W.C., and remittances should be made payable to him. Post Office Orders to be made payable at 422, Strand, London, W.C.

Foreign Subscribers, when remitting their subscriptions, are particularly requested to advise the Publisher of the name of the Bank on which the draft is drawn, and the number which is to be entered in the Bank Book, as otherwise much difficulty is very likely to occur in obtaining the name of the subscriber.

Office for Publication, and Advertisements, Nos. 35 and 36, Bedford-street, Strand, W.C.

NOTICES OF MEETING.

THE INSTITUTION OF MECHANICAL ENGINEERS.—Ordinary meeting, Tuesday, April 5th, at 8 P.M. Paper to be read and discussed: "The Application of Steam Power to Road Traction," by Thomas Aveling.

HOCKEY OF ENGINEERS.—Monday, the 4th of April, a paper: "On the Application of Steam Power to Road Traction," by Mr. Thomas Aveling. The chair will be taken at half-past seven o'clock precisely.

INSTITUTION OF CIVIL ENGINEERS.—The meetings will be held in the Hall of the Society of Arts, John-street, Adelphi (by permission of the Council of the Society of Arts), on the following Tuesdays, at 8 P.M.:—Tuesday, April 5th, meeting at 7.30, when tea will be served at 7 o'clock; and on Friday, April 8th, meeting at 7.45, and meeting at 8 o'clock. Subject for discussion, "The Application of Steam Power to Road Traction," by Mr. Thomas Aveling, Assoc. Inst. C.E. 1. Annual Report of the Council. 2. Election of Officers and of the Council. 3. Election of Members. 4. Election of Associates. 5. Election of Students. April 12th, meeting at 7.30, when tea will be served at 7 o'clock: and on Friday, April 15th, meeting at 7.45, and meeting at 8 o'clock. Subject for discussion, "The Application of Steam Power to Road Traction," by Mr. Thomas Aveling, Assoc. Inst. C.E. (Continued.) "On Peculiarities of Detachment of Steel and Wrought-Iron Plates," by Mr. Edward Woods, Assoc. Inst. C.E. "On the Engineering Features of Steel for Shipbuilding and Marine Engineering," by Mr. Edward Woods, Assoc. Inst. C.E. Ballot for the election of Members. April 19th, meeting at 7.30, when tea will be served at 7 o'clock precisely. "On Steel Rails," by W. H. White, Assistant Constructor of the Admiralty. "Experiments on Steel Ambrosium, Bessemer, and Siemens Steel," by Mr. Ernest Anstruther, Inspector of Machinery, Admiralty. "On the Influence of the Quality and Length of Specimens on the Tensile Strength of Steel," by Mr. Ernest Anstruther, Inspector of Machinery, Admiralty. April 22nd, meeting at 7.45, and meeting at 8 o'clock. "On the Manufacture and Testing of Rolling Stock," by W. G. Wilde, Assistant Commissioner on the Railway Department of the Board of Trade. "On the Construction of Locomotive Engines," by Mr. Joseph Tomlinson. "Permanent and Displacement in Relation to Strains in Ships among Waves," by W. John, Secretary to the Underwriters' Registry of Iron Shipping, Associate Institution of Civil Engineers. "On Steel Ingots," by Mr. Jacob Dowling (Dowlais). "On Steel Castings," by Mr. Jacob Dowling. "On Steel as introduced for Girders in the Bay of Biscay," by Mr. F. J. Bell, Assoc. Inst. C.E. Ballot for the election of Members. April 26th, meeting at 7.30, when tea will be served at 7 o'clock precisely. "Shipbuilding Investigations," by Charles Cail. A.M.I.E. "Shipbuilding a Science," by Mr. Charles Barker, Glasgow.

PHYSICAL SOCIETY.—Saturday, April 9th, at 3 P.M. "Experiments on Electrical Resistance," by Mr. Shelford Bidwell. "Notes on Thermal Electricity," by Mr. J. H. Gladstone and Mr. Tribe.

ENGINEERING.

FRIDAY, APRIL 1, 1881.

NAVAL ENGINEERS.

THE engineers in our Navy have, we think, good cause for the general dissatisfaction which has for a long time past prevailed amongst them respecting their position in the service, and it is much to be regretted that those at the head of our Admiralty should either wilfully, or through ignorance, fail to recognise the just claims of an important body of men on whom the efficiency of our war-ships so very greatly depends. We have on many occasions pointed out in this journal how, during the past few years, the duties of naval engineers have materially increased, both in extent and importance. In the early days of the application of steam power to our fighting ships, the responsibilities of a naval engineer were vastly different to what they are now-a-days. At that time an engineer's duties ended almost entirely to his engines, while the latter, in the majority of cases, furnished but auxiliary motive power, so that their failure was not of such paramount importance as it would be in most of our modern ironclads. Now-a-days, in addition to main engines and boilers of vastly greater power than formerly, the naval engineer is responsible for the numerous auxiliary engines employed in all parts of the ship, for turret engines and turning gear, for iron gun-carriages, and for hydraulic gear for working them, for steering, ventilating, distilling, and screw-lifting apparatus, for water-tight doors and appliances for working them, for fire extinguishing pumps and other apparatus, and (besides other details which we need not mention) for Whitehead torpedoes with the air-compressing pumps and other machinery employed in connexion with them. Taking the special features of modern naval warfare into account, it is impossible to overrate the importance of the various duties we have just enumerated, and we maintain that it is only just that an officer to whom such important duties are entrusted should have a standing in the service commensurate with the responsibilities thrown upon him.

Judging from some remarks made by the Junior Lord and by the Secretary of the Admiralty during the recent debates on the naval estimates, an erroneous opinion appears to prevail in high quarters that a good deal has been done of late years to improve the position of our naval engineer officers. That something has been done we admit, but that this position is generally considered on the occasion of the case we most strongly deny. We use the word "occasion" here advisedly. No one of the least practical knowledge who has examined a little carefully will attempt to dispute that the efficiency of such a complex machine in time of war depends almost entirely upon the skill and energy of the engineer officers in charge. In saying this we have no desire to disparage in the least the importance of other officers and crew. To the skill of these officers and men in their particular duties must unless backed up by the efficient working of the engines—all the skill and valour would be rendered practically useless. It appears to be unquestionable that the value of the service to be rendered the important position to which naval engineers may rise is fully recognised, but the facts remain, and the more they are fairly faced the better for the service.

When the numerous sons of our merchant princes is taken into consideration, it appears a most "penny wise and pound foolish" policy for higher naval personnels means to secure the services to our Navy of the most energetic and skilful engineers it can command. Admiralty authorities either do not, or will not, see this, and as a result it is evident that naval service is most unpopular amongst young-going engineers, and is almost universally execrated privately amongst the engineers now in the Navy. There has been recently circulated a printed statement in which the position of naval engineer officers of to-day, as regards rank and pay, is compared with that existing in 1865, and this document has received considerable attention from which that naval engineers are being fairly treated. From it it appears that, on the whole, engineer officers of to-day are in many respects worse off both as regards pay and position than they were eighteen years ago, while in any case the pay now given is far from being continuous especially—ridiculously inadequate when the responsibilities are taken into consideration. Altogether we maintain that the present position of engineer officers in our Navy deserves immediate and serious attention. As it is there are grounds for our Navy, and jealous of anything that militates against its efficiency, and under circumstances we trust that our Admiralty authorities may take an early opportunity of thoroughly reviewing the engineer branch of the service, and that they make such changes as will secure to engineer officers the rank and pay to which they are justly entitled, and will render naval service sought after instead of avoided by our most competent sea-going engineers.

ELECTRIC LIGHT IN THE CITY.

YESTERDAY evening was commenced throughout a large portion of the City of London a twelve months' trial of the application of electricity to street illumination, which is probably the most important and practical that has yet been made; and we venture to consider that the 31st of March, 1881, will on that account long be remembered as the beginning of a characteristic epoch in the history of electricity, and of the application of science to the requirements of the public.

Our readers will doubtless remember that as far ago as July last it was decided by the Commissioners of Sewers, after many negotiations, for some inscrutable though doubtless wise purposes, such matters seem) to invite tenders for the electric lighting of some of the main thoroughfares of the City, and on the 15th of the following month advertisements were issued by the Corporation, inviting tenders for lighting by means of the electric light "as an experiment" the following thoroughfares: New Bridge-street, Queen Victoria-street, Queen Street - place, and Queen - street, King William - street, Poultry, Cheapside, St. Paul's Church Yard (north side), Ludgate Hill, Blackfriars Bridge, Southwark Bridge, and London Bridge.

In reply to these advertisements, tenders were received from Messrs. Siemens Brothers, from the Anglo-American Electric Light Company (Brush system), from Mr. R. E. Crompton (Gramme), and from the Electric and Magnetic Company (Jablochkoff system), and in deference to wishes expressed by some of the competitors the area to be lighted was divided into three districts. The first or "Blackfriars Bridge district," included Blackfriars Bridge, New Bridge Street, Bridge Street, Ludgate Hill, St. Paul's Church Yard (north side), and that portion of Cheapside west of King-street. The second, or "Southwark Bridge district" comprised Southwark Bridge, Cannon-street Bridge, the lower part of Queen-street, and Queen Street-place, and in the third, or "London Bridge district" were comprised London Bridge, Adelaide-place, King William-street (including the open space round King William's statue, and St. Mary Woolnoth Church), the north side of the Royal Exchange, the lamps in front of the Poultry, that portion of Cheapside east of King-street, the upper part of Queen-street, King-street, and the Guildhall Yard; the three districts together presenting a line of streets to be illuminated of upwards of two miles and a half in length.

As we gave in these columns the particulars of the various tenders in our issue of the 19th of November last,* we need not enter them here further than to remind our readers that the contract for the Blackfriars Bridge district was given to the Brush Company, that for the Southwark Bridge district to the Jablochkoff Company, and that for the London Bridge district and Royal Exchange to Messrs. Siemens Brothers and Co. The particulars of the three accepted tenders were as follows:

District.	Number of Lights required.	Number of Lights to be Erected.	Total Cost.	Accepted Competitors.
1	600	750	1150	Anglo-American Electric Light Company (Brush system).
2	1500	1200	2000	Electric and Magnetic Company (Jablochkoff system).
3	2220	1455	3125	Siemens Brothers (Siemens-Gramme system).

Since these tenders were accepted the Jablochkoff Company, in consequence of legal difficulties, were compelled to withdraw from the competition, but they entered into arrangements with the Electric Lighting and Power Generation Company, who are the proprietors of the Lontin machine† and system to take up the contract for the Southwark Bridge district, and at the original estimated cost, namely 2000*l.*, and to light that district by the Lontin system. In consequence of this change of systems some little delay was unavoidable, but the company has undertakes to be in a position to light up the second district on the 1st of May next.

* See ENGINEERING, vol. xxx., page 501.
† *Ibid.* vol. xxviii., page 171.

covered with a sheathing of iron wires, as the cables lie along the broad outside ledge of the ballast track, and is not protected as the other circuits are by being laid underground. Adelaide-place, which forms a widened portion of King William-street, close to the north end of the bridge, is lighted by a single high light attached to the top of a very fine lattice pole, upwards of 120 ft. high, being fixed to the pavement of Thames-street, and rising to a height of over 80 ft. above the level of the approach to the bridge. The top of this slender and graceful pole is stayed by three ornamental iron wires to neighbouring buildings. In King William-street there are seven of the smaller lights, but the high light which illuminates the open space around the statue of William the Fourth, as well as that in front of the church of St Mary Woolnoth, contributes a large amount of the illumination to all the surrounding streets. Close to the Wellington Statue, in front of the Royal Exchange, rises a lattice pole, which supports a lamp which illuminates the great central space of the City bounded by the Royal Exchange, the Bank, and the Mansion House, and another is placed on the west side of Mr Tegetmeier's building and at the junction of Queen-street and the Poultry. Cheapside, including the Poultry, is lighted by four of the smaller lights in Queen-street by one, and King-street by two, while the space in front of the Guildhall is illuminated by one of the large lights supported on a lattice pole at the same elevation as the others. The light is the furthest from the generating station, being nearly three-quarters of a mile from Old Jewry-chambers, involving a length of electrical circuit of a mile and a half, that is to say, 3520 yards. The resistance of this, the largest length of cable in the installation, does not exceed one Siemens unit, which is a small fraction less than an ohm. We may add that the whole of the arrangements were carried out by Mr. Alexander Siemens.

[illegible] will complete a chain of electric lights extending from London Bridge station to Westminster Abbey, and a walk from London Bridge to Westminster and the Bank, Queen Victoria-street, Queen-street, Cheapside, Lombard-street, and the Thames Embankment would enable a person to compare the two systems of Siemens with one another, and with those of Lontin, Brush, Jamin, and Jablochkoff, coming to the British system again at Pelham Yard. Along the route, moreover, several points present themselves at which the several electric systems can be contrasted with the most recent improvements in gas illumination.

Besides the questions of effectiveness and economy of town illumination, there are other inquiries of interest upon which the coming trial will throw some light. It will, for instance, be interesting to know if the powerful electric currents, which will every night be flowing below the pavements in the City, will have any material inductive effect upon wires similarly laid carrying telegraph messages, or forming telephonic circuits. We should imagine that such currents must of necessity affect both telegraphic and telephonic instruments, and although the carrying of the return wire through the same piping would reduce the inductive effect to a minimum, still, unless the out-going and the return wires are twisted together, there must be many places at which the one wire, by being nearer to, would have a greater inductive effect than the other, and this, especially in the alternating circuits, would produce a vibratory inductive current in neighbouring telephonic circuits accompanied by a buzzing or humming in the telephones attached to it. We shall look forward with great interest to the tests which will be made on this point, as well as to the other results of this most interesting trial.

THE OTTO GAS ENGINE.

The action of Otto v. Linford, of the progress of the trial of which, before Vice-Chancellor Bacon, we gave a short note in our last impression, resulted on Wednesday last in favour of the plaintiff, but this decision is not necessarily final, and it is possible that the matter will be taken to the Court of Appeal. Under these circumstances it would of course be undesirable that we should express any opinion on the point in dispute, but merely place the general facts before our readers.

Many attempts have from time to time been made to convert the potential energy of a mixture of coal gas and air into useful mechanical work. When a mixture of coal gas with sufficient air to effect its complete combustion (which we shall call for a concentrated mixture) is ignited by an electric spark or flame, or other means, a chemical combination takes place which is attended with the development of a great amount of heat, which in its turn produces a sudden and violent increase of pressure of the products of combination. It follows, therefore, that the ignition of such a concentrated mixture within the cylinder of a gas engine must be attended with the following results, viz.: (1) A violent shock, requiring the parts of the engines to be very strong and heavy, and (2) a great elevation of temperature of the cylinder, the effects of which are twofold, viz., a considerable loss of heat and great wear and tear of the moving parts.

Engineering, May 1883.

ELECTRIC LIGHTING.

TO THE EDITOR OF ENGINEERING.

SIR,—Those people who have collected five years ago, when the directors of Paul Jablochkoff's Company were in Paris and London, almost simultaneously brilliant with the electric light, and the other discoveries of still greater interest which would follow, are now with each rapidity as to make it unsafe for the confidence of capitalists to advance in the adoption of the new terms for the purchase of the streets. There are at present no less than twenty-seven companies in the city of New York actively engaged in the business of transmitting electric energy along wires. Of these eleven are telegraph companies, having fire alarm and police telegraphs; four are electric light companies, including the Edison Company; one is a telephone company; and five are electric lighting and power companies. Several of these companies possess underground rights, and many have availed themselves of their franchises, notably the Edison Company, which has a complete system in successful operation under about sixteen miles of streets. It is clear, however, that twenty corporations, having substantially the same requirements, cannot follow the example of Edison Company and lay down independent mains, as the disfurnace of the streets would become an intolerable nuisance. It is the object of the committee, therefore, now on behalf of several corporations, to examine in the most thorough manner all such devices as are now before the public, and to report for the benefit of all of determining if a satisfactory system can be found, and if not, whether any system can be devised which will diminish the cost of installation to such an extent as to enable all to unite in a single system. Such a system, if perfected, would render it possible for a householder to be connected to either a burglar alarm, a messenger call, a telephone, an incandescent electric light main, a fire alarm, or telegraph wire without removal of the pavement.

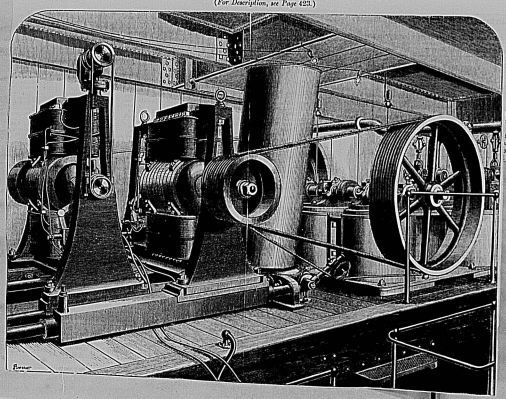
Yours obediently,
ALTERNATE CURRENT.

ELECTRIC LIGHTING NOTES.

A "committee of underground communication" has been formed in New York for the purpose of devising a feasible an ideal system under which every house can be supplied, on demand, with every form of electrical energy desirable, without delay, undue cost, or disfigurement of the streets. There are at present no less than twenty-seven companies in the city of New York actively engaged in the business of transmitting electric energy along wires. Of these eleven are telegraph companies, having fire alarm and police telegraphs; four are electric light companies, including the Edison Company; one is a telephone company; and five are electric lighting and power companies. Several of these companies possess underground rights, and many have availed themselves of their franchises, notably the Edison Company, which has a complete system in successful operation under about sixteen miles of streets. It is clear, however, that twenty corporations, having substantially the same requirements, cannot follow the example of Edison Company and lay down independent mains, as the disfurnace of the streets would become an intolerable nuisance. It is the object of the committee, therefore, now on behalf of several corporations, to examine in the most thorough manner all such devices as are now before the public, and to report for the benefit of all of determining if a satisfactory system can be found, and if not, whether any system can be devised which will diminish the cost of installation to such an extent as to enable all to unite in a single system. Such a system, if perfected, would render it possible for a householder to be connected to either a burglar alarm, a messenger call, a telephone, an incandescent electric light main, a fire alarm, or telegraph wire without removal of the pavement.

ELECTRIC LIGHTING ON THE S.S. "ARIZONA".

(For Description, see Page 423.)



which culminated in the financial difficulties of 1866 and following years, and the depression produced by the state of affairs rendered it impossible to carry out those lines. Soon after those lines were rendered unnecessary, for their abandonment. Mr. C. J. P. Cave, manager of the Brighton Railway, Mr. Grierson and Mr. Findlay, who represent on the Great Western and North-Western Railways respectively, decided to prove that if sanctioned the line could never be a financial success, that it under the most favourances could never be sufficient to pay the dividend upon the large capital required, and statistics founded on the instances of the existing line were put as traffic could not be counted upon large number of trains per day re-working arrangements. As soon as this been completed the town was cleared, misunderstood of the parties they were at the Committee were of opinion that had not been proved.

and Groombridge Railway Bill was

railways, each about twenty miles long, the first of those lines commences by a junction with the Berks and Hants line of the Great Western Company near Pewsey, and traversing the valley of the Avon, one of the most populous districts of Wiltshire, terminates by a junction with the Great Western Railway near Salisbury Station. This part of the scheme is chiefly local in character, and has similar objects to those of a scheme sanctioned in 1865 called the Wiltshire Railway, which, however, never made any substantial progress. The remainder of this year's scheme was a line from Salisbury to Southampton skirting the north side of the New Forest, and terminating by a junction with the Didcot and Newbury authorised line; by this a through Great Western route from the west, and eventually from South Wales to Southampton, would have been secured, but as far as the new line was concerned, an unnecessary duplication of railways in the hands of the South-Western Company would have resulted. These two companies, however, wisely entered into an agreement by which sufficiently independent access to Southampton has been secured to the Great Western Company by running powers over their rival lines for the greater part of the way, and by a junction between the line and the Didcot Company's line already referred to, which line is to be worked by the Great Western Company. This latter portion of the scheme has therefore been dropped, and, there being no opposition to the first portion, it has been referred to the committee on an unopposed Bills.

The Windsor, Ascot, and Aldershot Railway Bill is a similar to that which last year was the survivor of two introduced into the Commons, but was rejected by the Lords, and has for its object the construction by an entirely independent company (supported by the Great Western Company, who pay a portion of the cost of the application of it fails, but no portion if it successfully first of a line about ten miles long between Windsor and Ascot, joining the Great Western near Windsor and the South Western at Wood Station. In its route it passes near Clewer, Pittfield, and Winkfield, where there will be stations; thence from Ascot, in consequence of the decision of last year's Committee of the Commons, it will be parallel to the Reading and Reigate line of the South Eastern Company near Virginia Water, thence running powers over that line to Aldershot, and an alternative method of completing the communication between Ascot and Aldershot is provided for in the Bill, which asks for running powers over the South Western lines between those points. The South Western Company, whose Bill for a similar line was defeated last year, oppose, of course, as by this scheme access independent of their system would be given to Ascot, where at times there is considerable traffic. They are joined in their efforts by a gentleman owning an estate, which in his opinion would be detrimentally affected by the construction and working of the proposed line.

The Bill of the London and South-Western Railway Company is now under consideration by the Committee, of which Mr. Pertram is chairman, and the portion relating to the Netley and Fareham Railway has been passed subject to certain conditions to its compromise. The new short line about to be built long, connecting the Southampton and Netley and Hamble and Gosport lines of that company, thus completing another route between Southampton and Gosport and Portsmouth, avoiding the Eastleigh and Botley necessitated by that existing line of railway. There was some local opposition to the construction of this line, which, being the more direct course of a line sanctioned some years ago, and finally abandoned, but making a detour inland so as to cross the navigable waters of the River Hamble above an existing road bridge, and thus avoiding some of the principal points.

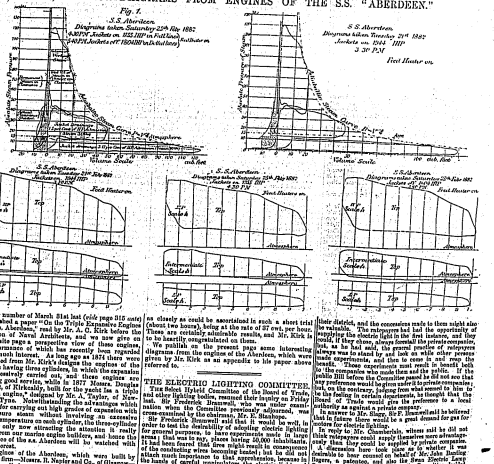
Mr. Lawson Gower's Committee have before them the East and West Yorkshire Railway Bill, which is another instance of the revival of a Bill of last session passed by the Commons but rejected by the Lords. By it a company is proposed to be incorporated to construct a main line about twenty miles long, which, commencing by a junction with the authorised Hull and Barnsley Railway near Drax, passes through Burton, Salmore, Lodmore, and Bedlewell, and terminates at Leeds. There are also branches to the Great Northern Railway at Ardsley and Lofthouse, and to the Midland Railway at Woodlesford. Between Burton, Salmore, and Leeds it traverses an extensive coalfield, and it is for the accommodation of this district that the line is chiefly directed. It has been stated that by it a saving of 2d. per ton would be saved in the carriage of coal to the port of Hull, and delays amounting to seven days in the journey of the trucks to and fro would be avoided. This line having laid out, for the whole length, parallel to, and at no point more than three miles distant from existing lines of the Lancashire and Yorkshire and North-Eastern Railways, those companies unanimously oppose its opposition.

By the Bill of the Midland, Birmingham, Wolverhampton, and Milford Junction Railway it is proposed to incorporate into a company a large number of subsidiary and gentlemen for the purpose of constructing railways of an aggregate length of some forty miles, with a capital amounting to rather more than a million and a half. The principal line commences near Craven Arms by a junction with the Craven Arms and Carmarthen line of the London and North-Western Railway Company, and passing through the town of Bridgenorth terminates by a junction with the Walsall and Wolverhampton line of the Midland Company near Willenhall. There are also junctions with the Central Wales Railway, the Shrewsbury and Hereford Railway, the Stour Valley, and main lines of the London and North-Western Railway. By these new railways, together with exclusive running powers over many lines in Wales, an important district would receive railway accommodation, and limestone would be brought from the Welsh quarries to the iron works near Wolverhampton. The route from the Cambrian system, by the aid of future extensions between Bishop's Castle and Montgomery, to manufacturing districts, would be shortened by twenty miles, and an alternative route as short as that at present by the Great Western Railway, would be opened up in the hands of the London and North-Western Railway between Llandeilo and Milford Haven.

THE ELECTRIC LIGHT ON BOARD SHIP.

There is no single field in which the electric light has attained as much success as in the lighting of passenger steamships. Its merits are recognised in its manifest means of decreasing the discomfort that always attends a voyage, as loss to a landsman, and gives it an immediate trial. Two great evils of ship life are the discomfort of space and want of ventilation, and both these are intensified after dark by the ordinary means of artificial light, as passengers congregate round the lamps, while there is no free overhead space into which the products of combustion can escape. Even in the Arctic Atlantic, with its temperate climate and constant air currents, this is severely felt, but it is only in the Red Sea or the tropics, where the heated air seems to stagnate, and the punkahs have to be kept at work over the heads of the passengers as they dine, to raise a semblance of a breeze, that the full significance of "the" smell of the lamps" can be realised. Consequently, while proprietors and manufacturers ashore have been waiting to see the course of events, and the progress of invention, shipowners have made larger and larger ventures until now it is understood that every new steamer of the leading lines shall be fitted throughout with electric light. This position has not been attained without great exertions on the part of manufacturers, for it is needless to say that an installation upon a ship is a very different affair from one on land. Instead of a large engine house with *plenty of space* for attendants and room for the use of long belts, there is usually assigned to the electrician a confined space partitioned off from a coal bunker, and in this both engines and dynamos must be arranged. In the early days this want of space was not so severely felt, because the illumination was effected by few lights, which, on quite comparatively little engine power, and hence it was usually possible to arrange the apparatus so that a belt of a reasonable length could be used to convey the motion from the engine to the generator. But the invention of the Swan lamp quickly changed all this; the power employed increased from 8 to 50 horse-power, while the available space grew no greater, and consequently other means of transmission had to be found. The Swan Company and Messrs. Siemens Brothers, between whom the bulk of this trade is divided, worked out the question in two different ways. The former firm adopted the Brotherhood three-cylinder engine, and coupling it direct to the axis of the dynamo-ring, dispensed

INDICATOR DIAGRAMS FROM ENGINES OF THE S.S. "ABERDEEN."



In our number of March 31st last (*vide* page 310 ante) we published a paper "On the Triple Expansive Engines of the s.s. *Aberdeen*," read by Mr. A. C. Kirk before the Institution of Naval Architects, and we now give on the opposite page a perspective view of those engines, the performance of which has recently been regarded with so much interest. As long ago as 1874 there were constructed from Mr. Kirk's plans the engines of the Propontis having three cylinders, in which the expansion was successively carried out, and those engines are still doing good service, while in 1877 Messrs. Douglas and Grant, of Kirkcaldy, built for the yacht of Mr. Ure a similar engine,* designed by Mr. A. C. Taylor, of Dunfermline-on-Tyne. Notwithstanding the advantages which it affords for carrying out high grades of expansion with high-pressure steam without traveling an excessive range of temperature on each cylinder, the three-cylinder system is only now attracting the attention it really deserves, and several marine engine builders, and hence the performances of the ss. Aberdeen will be watched with special interest.

The engines of the Aberdeen, which were built by Mr. Kirk's firm—Messrs. R. Napier and Co., of Glasgow—have three cylinders respectively 30 in., 51 in., and 70 in. in diameter, the stroke in each case being 4 ft. 6 in. The steam passes through the three cylinders successively, and is supplied at a boiler pressure of 125 lb. per square inch by two ordinary double-ended boilers, made entirely of steel, and each fitted with six of Fox's corrugated furnaces. The total heating surface is 7132 square feet, and there is no superheater.

As will be seen from our illustration, the three cylinders are placed in a fore and aft line, each cylinder having its own crank. The high-pressure cylinder is next jacketted, but the intermediate cylinder is jacketted with steam at 125 lb. pressure, and the low-pressure cylinder with steam at 15 lb. pressure above the atmosphere. The engine is fitted with Wolfe's feed-heater, and their general design, which is excellent, will be readily understood on reference to the illustration.

The Aberdeen is an iron ship 300 ft. long by 44 ft. beam, and 33 ft. depth, and when complete with 2000 tons of dead weight on board, a trial was made to ascertain and test the consumption with the engines developing 1400 horse power. Under these conditions the consumption of Pentfyrher Welsh coal was found to be but 1·29 lb. per indicated horse power per hour, the coal being weighed by Mr. Parker (of Lloyd's Register) and Mr. Dunlop, who happened to be on board. A further and shorter trial was subsequently made with the engines developing 2221 indicated horse power, the speed attained being 13·74 knots, and the consumption, as closely as could be ascertained in such a short trial (about two hours), being at the rate of 1·27 owt. per hour. These are certainly admirable results, and Mr. Kirk is to be heartily congratulated on them.

We publish on the present page some interesting diagrams from the engine of the Aberdeen, which were given by Mr. Kirk as an appendix to his paper above referred to.

* The engines of the Ina were illustrated in ENGINEERING, vol. xxvii., p. 194.

THE ELECTRIC LIGHTING COMMITTEE.

The Select Hybrid Committee of the Board of Trade, and other lighting bodies, resumed their inquiry on Friday last. Sir Frederick Bramwell, who was the principal witness when the Committee previously adjourned, was cross-examined by the chairman, Mr. E. Stanhope.

In reply to Mr. Dixon, Sir Frederick Bramwell said that in order to test the desirability of adopting electric lighting for general purposes, the Committee should insist that every area that was to be, places having 50,000 inhabitants. It had been feared that free wiring would be dangerous, but if the conducting wires becoming heated but to dull red attach much importance to that apprehension, because in the case of the careful manipulation the electric light could never give rise to such accidents. The same precaution existed against fire from gas, for that gas was introduced, and many persons lost their lives in consequence to have gas pipes laid in their houses. In no case did he think that any wires might be left exposed and really accessible with safety, though in other cases it would be dangerous to life to have any of them were not thoroughly insulated.

In answer to questions by Mr. Stroyan-Mackelyne, the witness said that the Committee should think that municipal authorities would be more likely to let either private companies or electric lighting companies do the work themselves, and when success had been obtained there would come in and buy out the companies who had been working them. The method of buying up the companies would probably be less than the amount expended in making the experiments.

In reply to Mr. Brooks the witness said that electric lighting was already established in Paris, Berlin, and New York. He could not say whether experiments on a large scale would be made in those cities. There was no doubt that the Government of France, in some cities, and in the electric light would there be in a position to offer places as the result of those experiments. It would be very desirable to experiment in all places where it was proposed to adopt electric lighting. He did not see that ratepayers would be injured by the introduction of electric companies established, even in competition with the local authority, because ratepayers did not supply themselves with gas, and the profits under the present time, although it was very likely that some companies granting of concessions to electric lighting companies, who, in consequence of making successful experiments, would have to be bought up, would sell their rights to local authorities at a ratepayers. It might be worth while for a corporation to pay a goodwill for the business of the private companies who wished to supply their district, and the concessions made to them might also be valuable. The ratepayers had had the opportunity of supplying the electric light from the underground mains, which, if they chose, they could themselves undertake, especially, as he had said, the general practice of ratepayers always was to stand by and look on while private trade experiments, and then to come in and reap the profits. These experiments must result in benefit both to the companies who made them and the public. If the public were to have the Committee put it to private companies, and if they were not willing to undertake the work, then, on the contrary, he would say that the Committee should recommend that the Board of Trade would give the preference to a local authority over a private company.

In answer to Mr. Hoare, Sir F. Bramwell said he believed that for electric lighting it would be a good thing to have a system for electric light and power.

In reply to Mr. Chamberlain, witness said he did not think ratepayers could supply themselves more advantageously than they could be supplied by private companies.

Mr. Chamberlain here read the clause in the Bill which enables the borough to lease the Local Electric Lighting Company's undertaking, and after consultation, the Committee decided not to hear Mr. Hopper. With respect to the Swan Company, as a new company had been introduced to the scheme, they decided to hear counsel on that, after the case for the Electric Lighting Company of the Strand Society.

Mr. Wm. Spottiswoode, Q.C., on behalf of the electric lighting committee of the Society of Arts, said that the Society of Arts had taken great interest in the progress of electric lighting for many years, especially during the last two years, and had been practically directing the experiments for lighting purposes, conducted by Messrs. Siemens, Crompton, and Swan. He would call Mr. Preece, the engineer-in-chief of the Post Office, to show that the Committee thought it would be better to encourage the system of particular inventors or companies as much as possible.

The witness, continuing his address, said he must be the last to say anything against the Board of Trade, and the word municipality might be the best, but private enterprise would be quicker. Their system went to prevent the electric lighting passed the experimental stage, and in lighting service passed the experimental stage, and in the general community. He could not say as to the Swan system, but the Committee had no connection with gas, although it was connected with the Edison system. Mr. Preece would be inclined to think there would be considerable advantage in connection with that of gas. He thought large buildings would be got by using the electric light, and that would be of great advantage to the public. The special advantages of the system of which he did not know a room, or within the limits of a second, and the witness thought that the system was agreeable. He thought that the Committee should not recommend that any special buildings should be allowed under the provisions, but that they should be left to the ordinary law. Any person, he thought, should be allowed to lay down electric lighting, and he had given notice of his intention to lay down a system in Brighton, and provisional orders are granted to him that if all parties consent, it was necessary to put the machinery of Parlia-

THE ELECTRIC LIGHT IN WARFARE.

During the winter of 1879-80 a great number of experiments were made at Chatham in order to test the efficacy of different electric lamps and machines for military purposes. Major Armstrong, Captain Abney, Lieutenants Barker, Darwin, and others were members of the Commission for carrying them on, and the well-known experimental ability of some of those gentlemen, coupled with the impartial character of the trials, give the results a special value. It is somewhat unfortunate, therefore, that the official account of those important experiments should first be made public in a foreign journal. We do not know how it has come about, but so far as we are aware, no English periodical has as yet been presented with the official report, while the French *Revue Industrielle* for April 27 contains a lengthy summary of it. To this article we must confine ourselves indebted for the following facts:

The dynamo-electric machines tested were those of Gramme, Siemens, and Wilde. The Gramme machines consisted of type D, driven directly by a three-cylinder Brotherhood engine of 14 horse power; type A, the ordinary pattern, driven directly by a three-cylinder engine; and type M similarly actuated. One Siemens machine of the large model was driven by a strap from an engine of 9 horse power; and two others of medium size were driven by a three-cylinder Brotherhood engine of 14 horse power. A Wilde machine of large size for giving alternating currents for the production of two lights was driven by a Brotherhood engine of 14 horse power, and a single-light Wilde, giving either a continuous or an alternating current was driven by a strap from a 6 horse power traction locomotive; in addition to these there was available an alternating-current Wilde machine capable of feeding six of Wilde's electric candles.

The lamps pitted against each other comprised Siemens' old and new patterns, the large Servia, Krupp's, Wilde's hand lamp, Sautter-Lemonnier's hand lamp (the lightest and simplest patterns), and the hand lamp of Captain Sales. The projectors were three of Siemens of 90, 60, and 30 centimetres (35½ inches, 24 in., and 12 in.) in diameter; of Siemens, of Wilde, and of Sautter-Lemonnier, Solomon, and Wilde. The carbons burned in the lamps were those of Sautter-Lemonnier, Siemens, Jolimon and Phillips, Carré, and Wilde.

The electrical measurements made were the electromotive forces of the generators, the intensity of the current producing the light, the difference of potentials between the two carbon points, and the consequently the resistance of the arc. Great care was taken to preserve the accuracy of these results, by a permanent system of apparatus, which was verified every day. The mechanical work absorbed by the generator was measured by an Allencock dynamometer; the intensity of the electric light was estimated by Rumford's method with red and green candles, the standard being an Argand burner with a Bengy regulator; and a telegraphic signal assured that the electric and photometric observations on the arc were made simultaneously. The carbon-points were also photographed to get the points of glowing surface.

The power of the projectors was gauged by shooting iron clad in red, white, and blue tinies at distance where the colours could be seen, confused, or plainly distinguished; but this method did not give sure results. A better plan consisted in erecting a screen 6 ft. square, and painted with letters about 900 yards distant, and turning it round the axis until the observers could just read the characters, when, at a given signal, the angle was measured. Like the former plan, this was dependant to some extent on the varying conditions of the atmosphere, and the best method was found to consist in planting poles in front of white screens and simultaneously comparing the depths of the shadows thrown by them on the screen when exposed to the projected beams of light. These methods, however, gave only relative results; and in order to get quantitative ones, the intensity of the shock of rays was measured at 600 yards from the projector by Rumford's photometer. In this way it has been demonstrated that Mangin's projector is much the best both in portability and power, and that the model of 90 centimetres in diameter throws twice more light than that of 60 centimetres.

The principal data furnished by the experiments are given in the two annexed Tables; the first showing the relations of speed, current, work consumed, and work utilised for the various machines tested; the second pointing out the relative merits of the machines as far as work utilised in the arc is concerned. It will be seen that the Gramme machines carry off the palm in this respect. It is noticeable also that diminishing the resistance of the arc produces a considerable increase in the work done in the other parts of the circuit, especially the machine, without producing a compensating increase in the light itself.

The advantages and disadvantages of the different machines are particularised in the official report on the trial. The two medium-sized Siemens machines are preferable for their yielding two distinct lights, of a brightness greater than the lights of other machines, with the exception of the C and D Grammes. But they are apt to burn up if not looked after; the coil warms up sooner than the electro-magnets; when they are combined the direction of the current readily changes, causing trouble and loss of time; and an irregular action of the lamp leads to strong sparks, to the waste of carbon, and consequently a rapid waste of time. In short, they require more experience to operate than the Gramme machines.

The Gramme gives a light conspicuously more intense than any other; and it can be entrusted to unskilful hands without fear of the wires being damaged or sparks produced. After going for six hours under the same conditions as the two combined Siemens machines, and with a current of 26.5 webers the temperature was only raised 60 deg. Fahr., whilst in the Siemens machines the rise of temperature was 110 deg. Fahr. at the coil and 50 deg. Fahr. at the electro-magnets, with a current of 55 webers. The electro-magnets of the Gramme machine heat faster than the coil or ring, therefore the machine is less likely to suffer from fear and wear. The high price of 3501, however, is an inconvenience, for it is once-and-a-half the price of the two Siemens machines.

The G Gramme is superior to all others in its simplicity of management, and it heats so lastily that, after going for six hours under the same conditions as the two Siemens, and the D Gramme, with a current of 83.15 webers, the temperature only rose some 30 deg. Fahr. The sparks are few, the efficiency is about 50 per cent.; the size of the machine is small, and its construction simple; the price (240l.) is about the same as the two Siemens machines, with their commutator; and the current can be utilised directly by means of a Siemens lamp. But the luminous intensity is only about 10,000 candles, or about the same as the two Siemens machines, and 80 per cent. less than given by the D Gramme. Further, the speed of 1200 turns per minute must bring about a rapid deterioration of the moveable parts of the machine.

The two combined *Gramme* machines of A type and only 170*l.*; they are free from excessive heating, and from sparks, besides yielding two lights; but the total quantity of light produced is only 18,600 candles, which is not enough for military purposes, and the direction of the current is apt to change, and cause trouble and loss of time.

Wilde's marine pattern has the advantage of connexions arranged to produce little waste of mechanism; it can be entrusted to persons little skilled in working it, the coils can be examined and re-wound without loss of time, and it furnishes two lights, but those lights are comparatively feeble.

As regards the lamps, the preference for military purposes is given, in that of Servia as the most convenient of the automatic sorts, and the inclined hand lamp of Sautter-Lemonnier is preferred for general purposes. These it will be seen, that the French apparatus has been found superior, not only as regards the machines, but the lamps, and also the projectors.

Engineering, Aug. 3rd 1883.

ELECTRIC LIGHTING NOTES.

THE Pilsen-Just and General Electric Light Company, Limited, have presented a petition for winding-up.

The Board of Trade having considered Major Marindin's report upon his examination at the New Leyton Vestry Hall, of the scheme for electric lighting promoted by the vestry, has decided not to sanction the same.

The New Zealand Electric Light and Power Company, which holds the Brush patents for that part of the world, has recently lighted the harbour of Lyttelton with sixteen lamps of 2000 candle-power (nominal), the contract price being 1000*l.*, subject to a two months' trial. Each lamp is fixed on a kauri pine, 30 ft. high, and protected by a reflecting hood. The conductor is laid underground in wooden piping for a distance of 1000 yards, and thence across the basin by a submarine cable.

Eberle's Restaurant, Dale-street, Liverpool, has been fitted up throughout with the electric light. The rooms are not lofty, and the incandescent lamps have been fixed to the moulded ceiling beams in conical reflecting shades of opal glass. The motive power is supplied by a gas engine, and a constant, steady light is insured by the use of Faure-Sellon-Volckmar accumulators. The work has been carried out by Messrs. Holmes and Veasey on behalf of the Liverpool Electric Supply Company.

On Saturday, July 21, Major Marindin, R.E., held an inquiry on behalf of the Board of Trade at the Vestry Hall, Walworth-road, with reference to the application of the Newington Vestry for a provisional order to supply the electric light within the parish. The vestry, ratepayers' committee, a working men's committee, and one or two property owners, were represented by counsel. It was explained that the order applied to the whole parish, but that it was only sought to make it compulsory over a small portion, the contemplated expenditure being 70,000*l.*, equal to an increase of the rates of about one penny in the pound. The opposition contended that it would be unfair to shopkeepers to light some districts and not others, while the property owners, who compulsion rates of their tenants, protested against having the latter increased. Mr. Shoolbred, the engineer to the vestry, defended his estimate, and declared that it would not increase the existing rates. The inquiry lasted seven hours, and at the close Major Marindin said he should report to the Board.

Among other schemes for enlarging the capacity for traffic of the Suez Canal is one which has been lately submitted to M. de Lesseps, and which aims at enabling ships to proceed through it with safety after dark, by defining the banks and the centre of the channel through the lakes. This project, which has been put forth by the National Company for the distribution of electricity by secondary generators, proposes to light the canal throughout the entire length of 102 kilometres by lamps placed on alternate sides every 250 metres, the total number of lamps required being 1360. The nature of the country through which the canal passes is such that it would be impossible, except at enormous expense, to effect the electric lighting of the locomotives in the usual way, being that special stations would have to be established every few miles for the supplies of engines and dynamos, and for the transportation of the steamboats charged with their crew and with the ship of supply. The engineers tested seven lamps, and at the close Major Marindin said he should report to his principals.

Among other schemes for enlarging the capacity for traffic of the Suez Canal is one which has been lately submitted to M. de Lesseps, and which aims at enabling ships to proceed through it with safety after dark, by defining the banks and the centre of the channel through the lakes. This project, which has been put forth by the National Company for the distribution of electricity by secondary generators, proposes to light the canal throughout the entire length of 102 kilometres by lamps placed on alternate sides every 250 metres, the total number of lamps required being 1360. The nature of the country through which the canal passes is such that it would be impossible, except at enormous expense, to effect the electric lighting of the locomotives in the usual way, being that special stations would have to be established every few miles for the supplies of engines and dynamos, and for the transportation of the steamboats charged with their crew and with the ship of supply. The engineers tested seven lamps, and at the close Major Marindin said he should report to his principals.

The originators of the project propose to use the system of Messrs. Gaulard and Gibbs, which was described and illustrated in our issue of June 1, 1883, and which consists in employing the main current generated at the central station for the sole purpose of supplying other secondary currents at a pressure at which a lighting station is to be erected, in the manner of an ordinary signal post. The main current, which is alternating in character, is made at each subsidiary station to circulate in a conductor wound round an electro-magnet, while side by side with this primary conductor is another in which secondary currents are generated by the reversals of the polarity of the core and the alternations of the primary current. Thus the main source of the main current is to act as a carrier of energy from the central to the subsidiary stations, where it is transformed into electricity of another potential suited for the purpose to which it is to be applied. By the use of a current of very high potential and of moderate intensity, circuits of very great length may be worked with small loss, and hence it is proposed that the whole length of the canal should be lighted from one station. In each of the posts which would be erected on the banks, and on each of the existing beacons in the lakes, there would be placed a secondary generator of such a size that it would, under certain assumed conditions of the primary current, suffice to feed an incandescence lamp of 80 candle power. Two of these lamps would be enclosed in each globe, with an automatic appliance to switch the second into circuit, if the first failed, while at the passing places, where there are always a few employés stationed, there would be a liberal supply of arc lamps fed by generators of greater power than those used for the incandescence lamps. It is estimated that 830 horse-power would be required, and that there would be 80 miles of submarine cable and 80 miles of land-covered conductor. One of the directors of the Canal Company, M. de Parville, has been to this country to inspect the apparatus and has reported very favourably on it.

THE HAWKES ELECTRIC LIGHT.

THE electric arc light of Mr. George Hawkes, of 2, Victoria Chambers, Westminster, is one of the most recent in the field, and judging by its performance it is also one of the best. It appears to combine in itself all the advantages of the Pilsen, or a still greater steadiness, with the simplicity and brilliancy of the Brush. The simplicity of the lamp is an important practical advantage, and its economical working is secured by a governor. While strictly adhering to the working of his lamp, Mr. Hawkes has had an eye to the appearance as well, although that is a point very often neglected.

The mechanism of the Hawkes lamp is illustrated in Figs. 1 and 2, which represent it in action. It is a clutch lamp of a very perfect kind, and is adapted to burn long carbons if required, so that it can be used for the lighting of streets as well as halls, factories, engineering works, and so on.

Figs. 1 and 2 are two vertical sections of the lamp in planes crossing each other at right angles. Fig. 3 is a sectional plan of the lamp along the line 1—1 in Figs. 1 and 2, and Fig. 4 is a sectional plan taken in the line 2—2 of the same figures. Fig. 5 shows a special device for cutting the lamp out of circuit.

The frame of the lamp consists of three metal bars A, A′, and A″, rigidly connected by vertical stems A², A³, and A⁴. The stem A², which is in connexion by the terminal below with the positive wire from the generator, is insulated from the metal plates, and the stem A³, which is in connexion with the negative wire through the plates A, A′, is insulated from the upper plate A⁴ only. This plate supports the mechanism for feeding the carbons and regulating the advance of the upper carbon C and holder C′, while the plate A supports the mechanism for regulating the advance of the lower carbon D and its holder D′. The carbon traverses a long hole in D, passing from the bottom of the lamp, and is prolonged at D by a liquid reservoir and a pendent guide-chamber.

We shall first describe the striking of the arc and the regulation of the upper or positive carbon. When the current is switched on the lamp it passes by the stem A³ and terminal *p* to the plates A, A′, and thence by the terminal *p*′ to the plate A⁴, which is in metallic contact with the stem A². From this it traverses the carbons and completes its circuit through the lower holder D′ and the stem A³. The current in the double-coiled electro-magnet E, situated between the plates A and A′, is therefore the main current from the dynamo or dynamos. Mr. Hawkes, however, has not contented himself with the mere striking of the arc on the principle of this electro-magnet in the main circuit. He has also arranged that a shall regulate without the motion of the magnet C. To this end he employs the following device: H is a called spring surrounding the upper part of the holder C′ and rotatable between two collars A B′, which also surround the clutch holder. The spring H is suspended from the guide frame C² by means of pendant wire that has freely passed the holder of the guide frame, and are each provided with a head to take a bearing on the guide frame. The holder C′ is attached to a pair of guide rods which, after passing up through the guide frame C², are connected together by a crosshead, upon which rests a regulating screw I, which is provided with a milled head to enable it to be set by hand. The spring H is intended to press upon the spring J of the electro-magnet when it is at rest, and by means of the screw I it can be so adjusted as to press upon the spring J with a certain force, so that when the current passes through the coils of the electro-magnet when it is switched on the spring J is attracted with a force sufficient to overcome the pressure of the spring H, and to draw the upper carbon C with it. The carbon C is thus drawn up, and on the current passing through a widening of the arc, the spring comes into contact with the armature, and consequently downwards, until its further extension is checked by the pendent collar A′, after which the armature alone falls by its own weight, and the upper carbon drops into contact with the lower one, thereby closing the main circuit. The electro-magnet again comes into play and re-establishes the arc at the proper length; however, to the spring device just described this action is extremely slow, and is not noticeable.

The lower carbon is released to maintain the arc by the pull of the electro-magnet E upon the armature K, from the weights pressing over two pulleys and attached to the rod K′. The advance is controlled by a clutch device of the following construction. The carbon-holder D′ passes through a hole in the plates A′ A, and between these plates of an electro-magnet F, which is in shunt or derived circuit as shown by the letter W. Attached to the armature D of the latter electro-magnet is a gripping-piece K which is carried by a vertical piece, and has an opening through it for each of the five passage upwards of the carbon-holder when the armature K′ is attracted by the magnet, and the gripping piece is thereby raised as shown in Fig. 1. Should, however, the strength of the current in the electro-magnet become enfeebled owing to a too long arc of the carbon, the resulting fall of the spring P presses down the corresponding gripping piece K, and causes the latter to bind upon the carbon-holder until the arc is sufficiently widened, and the derived current in the electro-magnet F is its normal strength.

The lower carbon is then unlocked by the predominating action of the electro-magnet on the spring, and the carbon advances as before.

The action of the spring H is regulated so as to limit the upward play of the armature D′, and to prevent its being drawn to the poles of the magnet. To serve this double purpose a hollow regulating screw P′ is provided, the lower end of which forms a stop for the head of the screw on the called spring P′, which is made fast to the armature D′. The hollow screw is tapped to receive an elongated screw P², which projects down through the called spring so as to form a stop to the rising armature. By the adjustment of the screw P² the force of the spring is regulated so as to counterbalance the energy of the electro-magnet to any desired extent, and the play of the armature D′ between the poles limited. The piston P′ moving in a well (W) of viscous liquid, such as glycerine and water, gives additional smoothness to the working of the lamp.

The device employed by Mr. Hawkes to cut out a lamp from a circuit when some accident has befallen the carbons, is a very simple and ingenious one. It is attached from the top plate A⁴, and resting on it is a strip of metal K, which is in metallic connexion with the stem A³, and whose other end of the armature C′. A similar strip of insulated metal K² is connected to the other stem A². The armature D′ at the point which overlie the strips K K′ is fitted with platinum contacts. While the lamp is in action, the armature being held up by the attraction of its electro-magnet in clear of these insulated metal pieces, but as soon as an undue resistance is offered to the main current, the power of the electro-magnet is overcome by the spring H, and the armature is dropped down and short-circuits the current by the strips K, K², as shown in Fig. 5. The lamp is thus cut out of the general circuit.

HAWKE'S ELECTRIC LAMP.

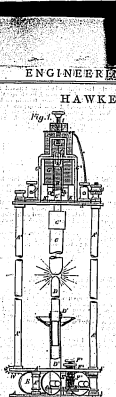

Fig. 2.

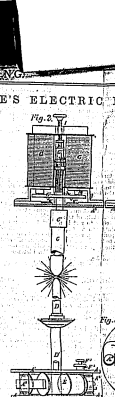

Fig. 3.

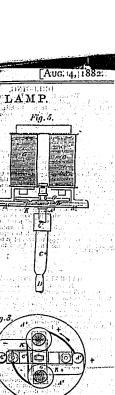

Fig. 5.

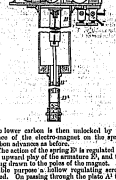

Fig. 4.

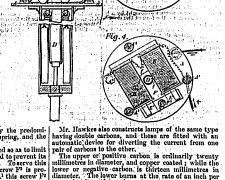

Mr. Hawkes also constructs lamps of the same type with double carbons, and those are fitted with an automatic device for diverting the current from one pair of carbons to the others.

The upper or positive carbon is ordinarily twenty millimetres in diameter, and copper coated; while the lower or negative carbon is thirteen millimetres in diameter. The lower burns at the rate of an inch per hour; but it can be made as long as to burn for forty or fifty hours. The lamp is stated to yield a light of 9000 candle power when fed by an A Gramme machine consuming 25 horse power.

MANCHESTER RAILWAY SIGNAL.—A new machine for the manufacture of railway spikes was recently exhibited in operation at the Manchester Exhibition of the American Union. A rod of metal is automatically fed into the machine from the rolls by means of a table and a "gripper," and at the end of the revolving of the handshaft, the spike blank is caught and firmly held by a suitable arrangement, while a pair of reciprocating cutters nibble off the rod, and the required length is measured. Next it forms the head, and the spike is then released, and carried forward to the die, where the point is finished, and the return motion the spike is thrown out of the blank holder by a rapidly acting "knocker," when it falls to the floor, and the table goes back to the cutter to receive the next spike. All these motions are completed in a single revolution, the speed of the machine being at the rate of 60 revolutions per minute. Three spikes per minute are produced by each machine. Three of these machines have been constructed, which, when set to be constructed, will be brought into operation at the works of the Andrew Clemens Iron and Steel Works, at Moundsville, West Virginia. For several years before his death the late Mr. Kloman spent a large amount of time and money in perfecting a machine of this kind, and the above is his invention completed and further improved by his successors.

EDISON ELECTRIC LIGHT FITTINGS.

The Edison generators are shunt wound, that is, the coils of the field magnets are excited from a current circulating from the brushes, the armature, and hence regulation is far from perfect, and when a considerable proportion of the lamps are turned out, say 50 per cent., there is a marked increase in the brilliancy of the remainder, and the current passing through them attains an intensity, which if allowed to continue would shorten the life of the filament. To prevent this a regulator is supplied with each installation, and this requires to be adjusted from time to time when the variations of a pilot light or the deflections of a galvanometer indicate that the difference of potential between the poles differs from the normal. This regulator (see p. 236, Fig. 1) consists of a box of resistance coils joined up in series, and so arranged that by the movement of the handle any number of them can be included in the field magnet circuit, and so add to its electrical resistance, causing a corresponding decrease in the current flowing through it, and consequently reducing the intensity of the magnetic field. From the junction between each adjacent pair of coils a conductor is led to a contact piece on the top of the box, and a finger piece, pivoted at one end, connects the adjacent piece of each pair of holders to the armature. On commencement of the first coil is connected to the first contact piece, and the end of the last coil to the last contact piece. The positive conductor from the pole of the armature is coupled also to the first contact piece, and the conductor leading to the coils is joined to the spindle upon which the handle turns. Thus, when the handle is at zero the current passes through it from the first contact piece without traversing any of the resistance coils; when it is moved (say) 90 deg. one-fourth of the coils are included in the circuit and the current must circulate through them before it can reach the handle and proceed to the magnets.

In this country the use of self-regulating generators is gradually displacing devices of this kind, but in theatres and places of amusement where many applications of illumination are required, they will probably always be used. Fig. 4 illustrates a combined water and gas bracket as erected in the Bijou Theatre, Boston, U.S., by the Edison and Swan United Electric Lighting. The state of nervous apprehension which has been created in large audiences by the fearful disasters which have occurred in theatres during the last few years, has rendered them peculiarly liable to panic, and where there are but few cases where electric light installations are so organised that total extension is an impossibility. Therefore, as managers naturally decline to place entire dependence upon electricity, the Edison Company has lately faced the situation and has brought out a fitting which admits of the use of both illuminants, either of which can be turned up or down with equal facility.

Figs. 2, 3, and 4 are illustrations of three other varieties of electric light fittings used by the Edison Company for Isolated Lighting. Fig. 2 shows an inexpensive form of jointed bracket with shade. The joints are mechanical, not electrical, the current being conveyed by a flexible cord, and they are provided with thumbscrews by which they can be set in any position of very convenient provision, as it allows of the use of long branches. In dwelling houses, where there is much greater scope than in gas brackets, for, although much greater scope than in gas brackets, for, although it is folly unhanging the gasaliers to bring a gas flame down to the level of the table, an incandescent lamp may be placed in the most convenient position where it can be found, provided the direct rays which can be found, provided the direct rays are screened from the eye. Fig. 2 shows an epergne are screened from the eye. Fig. 2 shows an epergne with four lamps, the design representing four cherubs which are set in a bouquet of metal-work. Fig. 5 is a full fitting of 16 lamps, the whole enclosed in large globe to protect them from dust and injury.

Advertisements of Miscellaneous, &c.—There were received last year 1,000 letters, 1,000 telegrams, 1,000 parcels, 1,000 cheques, 1,000 bills, 1,000 receipts, 1,000 orders, 1,000 invoices, 1,000 cards, 1,000 envelopes, 1,000 stamps, 1,000 pens, 1,000 pencils, 1,000 rubbers, 1,000 rulers, 1,000 boxes, 1,000 bags, 1,000 umbrellas, 1,000 hats, 1,000 coats, 1,000 boots, 1,000 gloves, 1,000 ties, 1,000 shirts, 1,000 collars, 1,000 cuffs, 1,000 studs, 1,000 buttons, 1,000 braces, 1,000 trousers, 1,000 waistcoats, 1,000 jackets, 1,000 caps, 1,000 scarves, 1,000 pins, 1,000 rings, 1,000 watches, 1,000 chains, 1,000 seals, 1,000 keys, 1,000 locks, 1,000 doors, 1,000 windows, 1,000 walls, 1,000 roofs, 1,000 floors, 1,000 ceilings, 1,000 lights, 1,000 shades, 1,000 globes, 1,000 chimneys, 1,000 burners, 1,000 wicks, 1,000 oil, 1,000 gas, 1,000 electricity, 1,000 batteries, 1,000 wires, 1,000 switches, 1,000 fuses, 1,000 meters

Engineering, Aug 31st 1883

THE EDISON CENTRAL STATION AT MILAN.

THE rapid development of industry in the last few years in Italy is well exemplified by the ready adoption in that country of telephones and of the electric light. In no country, America excepted, is the telephone so universally used, and the electric light is finding its way into many of the large stations and manufactories.

After the Paris Exhibition a committee of the principal banks at Milan investigated the subject of electric lighting. Professor Colombo and Mr. Gaul, engineer, both of Milan, were appointed as experts. They visited Paris and England, and the result has been that a central station has been constructed, which, with its single exception is that of Mr. Edison at New York, is the largest in the world.

The system adopted here has been also that of Mr. Edison. No company has yet been formed, and the plan proposed by the banks is very different to that pursued in the launching of companies in London. The Committee of the banks has devoted a sum sufficient to make an experiment with an installation of 6000 lamps. The entire work, however, is done upon the basis that it will be permanent. The company will only be launched after the plant has been worked long enough to prove what can actually be done upon a large scale. The speculators who formed the companies in England would undoubtedly look on such an operation with something of contempt, but the public and those who actually desire to see electric lighting succeed, can only bestow credit for this manner of procedure.

Had such methods been pursued in England, the discredit that has fallen upon electric lighting would have been avoided, not to speak of the financial aspect of the companies in this country, which is now generally understood; as many small installations have been made with agricultural ports to the engines and with ordinary engine-drivers as "engineers," that it is supposed to be necessary to have small lamps or gas somewhere to resume where electric lighting is used. An inspection of such an installation as the one it is proposed to describe here-in-after forwards convincing that electric lighting will be a commercial success; for the illumination is so much better than with gas, and the dirt usually attributed to electric lights so wanting, that the public would not be without the light at scarcely any price.

Many of the claims made for Edison by his supporters are ridiculous, but the allegations of those concerned in the industry of electric lighting are due to him, because at a time when are lighting was the only practical means and incandescent lamps impossible commercially, he must set himself to work to develop a complete system which could be used instead of gas.

Milan is peculiarly well adapted to electric light in its present state. The principal shops, theatres, cafés, and clubs are all in or near the magnificent "Galleria" of Victor Emmanuel. Nevertheless several kilometres of conductors are already laid. The station itself is a three-story building erected specially for the purpose on the site of the Theatre of Saint Radegonde. The lowest floor is three metres below the ground level. This floor is occupied by the dynamos and regulators, and by a test board for 1500 lamps. The boilers are located on the floor above, and are supported directly on cast-iron columns resting on a solid foundation. The upper floor is used as store-room, and a small portion is divided off for a laboratory. In a vaulted room under the courtyard is located an engine for driving a centrifugal blower, and a pump to be used as an adjunct to the Körting injectors feeding the boilers.

Four Edison dynamos, each capable of supplying 1200 Edison lamps, and of the type we illustrate on another page of the present issue, are already in place, and provision is made for adding several more, so that the design when carried out will embrace a greater number of lamps than even the station at New York. The armatures of the machines are 27 in. in diameter, and 61 in. long. The shaft is of steel 72 in. in diameter, and of a total length of 109 in. The journals are 6¼ in. in diameter, and 15 in. long, running in Babbitt metal bearings in brasses supplied with a continuous water circulation. Provision is made for an air blast to be applied to the armatures to keep it cool. The commutator is so nicely adjusted to its requirements, that notwithstanding the size of the current, no sparks of appreciable size are perceptible. The steam is furnished by Babcock and Wilcox boilers aggregating 1000 horse-power, and are worked under a pressure of 120 lb. All of the engines are connected directly to the shafts of the armatures. Two of the engines are Porter-Allen with cylinders 14¼ in. in diameter, 16 in. stroke, run at 300 revolutions per minute, and have a piston speed of 1023 ft. per minute. The other two engines already in use are by Armington and Sims. It is supposed that the latter will give better results when two dynamos are run together on the same circuit. They have 15 in. diameter cylinder and 15 in. stroke.

The weight of each dynamo with its engine is as follows:

	lb.
Base-plate	10,500
Dynamo	44,000
Engine	6,450
	61,450

The regulation is effected by changing the intensity of current circulating about the field magnets. The dynamos are all regulated together by means of a variable resistance introduced into the field. Each switch is driven by a lever and rod working into a corresponding gear keyed to a shaft. This gearing insures an even regulation. The indicator of the strength of the current passing into the lamps consists of a high resistance magnet, placed in derivation and balanced against a counterspring with variable adjustment. The magnet is supplied with "high" and "low" points working in separate lamp circuits through a small relay. Two coloured lamps are in these circuits; one or the other burns as the current is too strong or too weak. When either of the lamps is burning a vibrating bell sounds an alarm. A change in current sufficient to sound an alarm is known to scarcely sufficient to be noticeable to the eye. The conductors are copper rods with connections specially made for the purpose, so that no mistake can easily be made in laying them even by inexperienced workmen.

Professor Colombo is still the technical representative of the Committee, Mr. J. Lieb, formerly of the Brush Company of Cleveland, Ohio, and now of the Edison Company, is the engineer who has made the installation, and is now actually in charge. The effect of incandescent lighting in shops is well known to be particularly referred to, but when shop after shop has the group of incandescent lamps burning fruitlessly, and when the station from which the light is supplied is put up and watched with such care that it is difficult to see how any mishap can occur, the most sceptical must see that electric lighting can be made something more than "experimental."

Engineering, August 31st 1883.

ELECTRIC LIGHTING NOTES.

THE Edison Company for the Electric Lighting of Europe announce that they have erected 118 plants, aggregating a total of 41,780 lamps, and that there have been installed by other Edison companies in various parts of the world 138 plants with about 28,800 lamps, thus making 257 isolated plants with a total of 71,715 lamps.

The electric lighting of H.M.S. Alabaster, which has been carried out by the Edison Company, is effected by means of 16 dynamos upon which there are fixed 112 half lamps, (16 candle power) and 208 half lamps (8 candle power). There are 12 full lamps in the engine room, 16 in the lobby below, 7 in the shaft alley, and 47 in the upper saloon; 7 half lights on the saloon's access deck; 64 over the troops' mess tables forward, 27 in the saloon, 30 on the lower troop deck, and 26 on one of the pavilions.

The Edison Company, represented in Scotland by Mr. C. T. Grant, of Glasgow, has obtained the contract for lighting three fine steamers of the New Zealand Shipping Company's fleet. The first of these vessels, the Tongariro, has just been launched from Messrs. John Elder and Co.'s yard. The latest additions to the Clan Line have also been fitted with electric lighting plant by the same company, the new means of illumination being employed for side and cargo lights, as well as in the cabins.

Since the date of our article upon the electric lighting of the Fisheries Exhibition another arc lamp has made its appearance. It is the invention of Mr. F. L. Pyke, and six of them are suspended in the Western Quadrant, where they burn very satisfactorily. The feed of the carbon is controlled by a pendulum after the manner of the Siemens and Hochhausen lamps, which is in the means for holding and releasing the pendulum that the novelty lies. Instead of a detent, friction wheels are sometimes forced to lift, and catch a certain amount of friction, a varying magnetic attraction is brought to bear upon an armature attached to the pallets, the coils of the magnet being cut out of circuit by a defector relay when the lamp is running at normal resistance. By the use of double contacts, one of which is broken before the other, the additional effect of the spark which accompanies the rupture is confined to one pair of points only, and the other is always kept clean. The lamp is well and strongly made, and appears well adapted to stand rough or careless usage.

The system of town lighting by means of electric lamps mounted upon high masts or towers, which has found an extensive application in America, is now being tried in the Horticultural Gardens, South Kensington. A wooden framework 200 ft. high has been erected, and upon this an iron lattice pole 80 ft. in length is fixed, carrying a total height of about 280 ft. At the top of the tower there are suspended six Brockhouses arc lamps, fed from a generator in the night-light department of the Fisheries Exhibition, and each of 4000 candle power. Considering that on the dark clear nights there have prevailed, the light has have a most satisfactory appearance, and it is very easy to form an accurate judgment of their maximum effect. From the foot of the tower to the western quadrant is about 400 ft., and at that point it is possible to read a book printed in type of the size in which these notes appear, when the light falls directly upon it. This corresponds to the illumination afforded by a street lamp at a distance of about 60 ft. The gardens near the base of the tower are brilliantly lighted, and any kind of outdoor occupation might be carried on in them without difficulty. At about 300 ft. distance the shadows begin to be very distinctly noticeable, and great care is needed in passing from the patches of light into those of darkness, because the glare is for the moment too dense to be penetrated by the eye. While the grounds are put to their present pleasant uses, they are filled by a crowd who are enjoying the cool evening air and the music of the bands that play to advantage from other points, and, with a moonlight, effects of singular charm of this, the most agreeable entertainment which has been provided in London for many years. But if the space were devoted to business or rapid circulation it is evident that a much more useful result might be gained by distributing the lights more equally over the area. Unfortunately they are only half the height of those commonly used in America, and thus the shadows are longer and more obtrusive, but still they are higher than it would be practicable to keep them in this climate during nine months of the year. The experiment of the City lighting showed that even 50 ft. was too great an elevation during the winter, and that at little more than half that distance there was a loss of brilliancy.

Engineering, Sept 5, 1883.

THE EDISON SYSTEM IN NEW YORK.

After a long series of delays, the Edison Electric Lighting Company of New York has completed and put in use a system of house illumination extending over a part of that section of the city marked out about eighteen months ago, as the site for the first great experiment in public lighting from a central station. Of course we must wait to see how this experiment stands the test of a few months' experience before we can know whether Mr. Edison has really demonstrated the economic practicability of this mode of lighting. Meanwhile, it is worth while to place on record a few facts concerning this trial, the failure or success of which will be a matter of vast importance to gas manufacturers. The area to be lighted is about one square mile, but scarcely one-third of this is yet supplied. It comprises that part of New York between Ferry and Wall-streets on the north and south, and Nassau-street on the west, the eastern limit of the section being the East River. With the general details of the Edison system, our readers are well acquainted, though we may be sure that so fertile and restless an inventor will be constantly introducing new details and devices, so that the installation will possibly never reach its fullest stage of development. The general features of the station, the views of conductors and lamp fittings, may be described very briefly. A large building on Pearl-street, near Fulton Ferry, was acquired for the station, and contains the steam power, dynamo machines, and miscellaneous apparatus. The floors for the machinery are entirely independent of the building, and are carried up four stories in height. Six special generators of the largest size, and substantially of the type illustrated by us on page 377 of our last volume, are now at work. The armature is 27·6 in. in diameter and 6 ft. in length, it weighs over 4 tons. The total weight of each machine is somewhat over 30 tons, including the engine, which is coupled direct on to the armature shaft, and runs at a normal speed of 350 revolutions; these engines were made by the Porter-Allen Engine Company of Philadelphia, the engine bearing name-plates of factory built by the Edison Electric Light Company of New York. Steam is supplied by four Babcock and Wilcox boilers, each of 250 horse power. The maximum capacity of each generator is 1000 lamps of 16-candle power, though it is not intended to work them higher than 1200 lamps. The current runs from all six generators into two large copper bars, to which are connected the various conductors or street mains. Each dynamo can be cut out of the circuit by an ingeniously arranged switch, and visual demonstration of the efficient working of the generators can be made at any moment, as follows: In the station is placed a battery of a thousand 16-candle lamps, arranged in two groups, and these can be thrown into circuit with any one of the generators. If these lamps are brought up to the normal standard of brilliant incandescence, the generator is evidently working properly, and the cause of any interruption must be looked for elsewhere. The generators are also each provided with a series of resistance coils controlled by a steady switch, and an indicator enables the attendant to judge of the strength of the current. This indicator consists of two incandescent lamps, one enclosed in a blue, and the other in a red bulb. When the current-blue lamp becomes lighted, but when the field magnets are not sufficiently excited, the red lamp is brought to a state of incandescence. In normal working neither lamp is lighted. In the section now being lighted there are laid about fourteen miles of street conductors, which will supply the current through service wires to about 10,000 lamps, fitted up at present for the consumers. The arrangements within the houses are substantially those which we have described and illustrated, including the meter for recording the value of the electrical energy used by the lamps. On Monday last 5000 lamps were lighted up in various dwellings and offices, including the buildings of the *New York Herald* and *Times* newspapers. Probably it will be some time before all the subscribers on the section will be supplied, since the existing plant will have to be more than duplicated and will even then—if the working capacity of each generator be only 1200 lamps—be working with insufficient reserve power. It is claimed for this installation that the light will be supplied at a lower rate than gas, and this may easily be the case, for gas in New York is very costly. It is claimed also that the consumers will have no more difficulty or trouble in manipulating the lamps, than they have been accustomed to with gas-burners or oil lamps. This too remains to be seen, and if we are fortunate enough a few months hence, to obtain a really accurate statement of cost, of failures, and of practical difficulties, we believe it will be demonstrated that the Edison installation has not by any means thoroughly solved the problem of domestic electric lighting, but it will have rendered an invaluable service in developing defects and difficulties of which at present we are in ignorance. The question of cost is of high importance in this country, where, so far as experience indicates, the expense of electric lighting by incandescence is much greater than that of gas. On the other hand, it has advantages hard to over-value—coolness, purity and steadiness of light, and a total absence of vitiated air, destructive to many objects and detrimental to health. These are advantages for which a large body of consumers will be prepared to pay so soon as it is demonstrated that electric lighting by incandescence can be permanently relied upon.

Engineering, Sept. 30, 1881.

THE ELECTRIC LIGHT AT SOUTH KENSINGTON.

It is so difficult to obtain actual details of the cost of the electric light, and of its comparison with gas, that the following information will be read with considerable interest. It is extracted from the report just issued of the Science Reporting, Mr. the Assistant Director of the South Kensington Museum, who is specially entrusted with the lighting of the building.

"The total consumption of gas in the Museum schools, &c., at South Kensington, has been 20,000,000 cubic feet, nearly.

"The consumption at South Kensington shows a diminution of 1,750,000 feet with the previous year, of 2,750,000 ft. with 1879. The diminution is accounted for by the fact that since 30th September, 1880, the west side of the whole of the Lecture Theatre has been lighted by the electric light. The weather was unusually fine, and the lighter time in the previous year. The price was reduced from 3s. 6d. to 3s. 4d. on the first of January.

"Sir Frederick Leighton, P.R.A., having expressed his fears that the mural painting recently executed by him in the Lecture Theatre Court might be injured by the gas, it was decided to try the light in the court by the electric light. The 'Brush' system, which has been very largely introduced into this country from America, was applied, at the request to be that least suited for the purpose, and a dynamo-electric machine and eight lamps on this system were therefore purchased to light up the eastern half of the court. The machine was driven by the gas engine, and the result was the most satisfactory that it was determined to extend the lighting to the whole court. It was found that as the gas engine is not sufficiently powerful for this purpose, a semi-portable steam engine was purchased for the purpose from Messrs. Hammond, Ipswich, and placed in a temporary shed between the office building and the South Cities Museum, and towards the end of June the lighting of the whole court was commenced. On the 1st of July the whole court was lighted.

"The light is, as the whole audience can testify, that is not so nicely as could be wished, and it is quite unsuited in quantity of light to and perhaps to decoration. The present machine, however, is incapable of working more lamps. Three lamps are suspended from the roof, and are raised and lowered by means of cords, which have proved but an inconvenience at the court. It has, however, saving the expense of gas, done away with those cords, which will be applied after the present Exhibition is finally removed. This generally may now be taken as safely as the electric light has been worked without any accident for so long.

"Between the 23rd of June and the 31st of December the 16 lamps were at work on 97 nights for a total of 2320 hours; the total consumption of coal (Hartley), including what was used in lighting the fires, was 10 tons 13 cwt. 3 qrs. 14 lbs.'s work. The engine has been 20 and 21 horse power, but is capable of working up to double this power; it will therefore be well to drive a second machine as well, and no doubt we shall get a comparative diminution in the consumption of coal, which is even now lighter than on engine of this class. The nationalis expansion gear of Messrs. Hammond, which is the best of the kind we have had satisfactory account, the speed of the machine, as shown by the tachometer attached to it, being perfectly regular.

"The only actual calculation of the relative cost of the electric light has been to those of the stokers, which amount to 20s. a week. The engine fitter who looks after the engine has replaced a gasfitter.

"The working expenses referred to has been as follows:

	£ s. d.	£ s. d.	
Carbons ...	16 3 0 at	1	0 per hour of lighting.
Oil, cotton waste, &c. ...	4 11 6	0 3	,, ,,
Coal ...	11 14 6	0 0 8	,, ,,
	32 14 0		,, ,,
Wages ...	31 7 6	1 11	,, ,,
Total ...	63 2 0	3 10	,, ,,

"The consumption of gas when used to the rate of 10s. an hour would for the same period have been 2671. 6s. The saving in working expenses has therefore been 207l. 6s., or at the rate of about 63l. per annum.

"The costs are as follows:

	£
Cost of dynamo-electric machine ...	400
,, of lamps and fixing; conducting wires, &c.	284
Cost of steam engine and fixing; shafting, belting, &c....	420
	1104

"As, however, the steam engine is capable of driving two such machines, the cost of the machinery and apparatus for lighting the court may be said in round figures to have been 800l., on which outlay the saving at working expenses, as compared with gas, represents 42 per cent. per annum. The machinery at present shows no sign of deterioration from use, nor do I see any reason to expect any great expense on that account. I hope that, from our experience we may obtain greater steadiness in the light, and perhaps even some slight diminution of working expenses.

"I propose next to try similar lamps in some of the picture galleries, and in the Art Schools, in which latter there are great complaints of the bad state of the atmosphere in the evening from the use of gas. I hope also before long to be able to try some of the incandescence lamps of Swan or Lane Fox, which promise to be very suitable for the reading-room, and perhaps even for the Show."

Engineering Oct. 24th 1879

ELECTRIC LIGHTING.

The following resolution was placed on the agenda paper of the Court of Sewers, for discussion at the meeting of Tuesday last: "That the Commission, become the undertakers for the supply of electricity under the provisions of the Electric Lighting Act, 1882, and do apply for a provisional order or license, if as they may be advised, and that an intimation of the above course be given to the Board of Trade and the companies and persons who have served notices of their intention to supply, and that all other applications for provisional orders, so far as the City is concerned, be opposed accordingly."

In the course of the meeting, the Streets Committee stated that they had carefully considered the various applications that had been received for granting the right of private lighting to companies having contracts for street lighting in the City. One important point they had referred to an eminent electrician to report upon. This was whether it would be practical to lay in the same trench boxes of various companies working different systems, in such a way that any one act of conductors would not affect any other act, and also whether any type of conductor could be made use of for lighting by any system. The report of the committee following resolution was carried: "That the Commission become the undertakers for the supply of electricity under the provisions of the Electric Lighting Act, 1882, and do apply for a provisional order or license, as they may be advised; and that an intimation of their purpose be given to the Board of Trade and the companies and persons who have served notices on the Commission of their intentions to apply, and that all other applications for provisional orders or licenses, so far as the City is concerned, be opposed accordingly."

The following alterations have been made in the rules issued by the Board of Trade in August last in connection with Section 9 of the Electric Lighting Act, 1882:—Rule V.—The words "the lands which the undertakers are by law empowered to take for the purposes of the undertaking" have been omitted. Rule IX.—The wording of the first few lines of this rule have been altered in order to make the meaning more clear.

The Gas Committee of the Birmingham Town Council have approached the question of electric light in a very liberal and practical manner. Assuming that the introduction of it necessary to be attended by the Gas Undertaking agent, they do not fear that the vested interests will suffer. In order to secure the greatest advantage for electrical skill, they recommend that it should be tried under the following favourable conditions, and they distinctly point out that the success or failure of electric lighting elsewhere should not be allowed to prejudice the Birmingham experiment. Bearing in mind the importance of the problem, and the very probable benefits that may accrue to consumers by the substitution of electricity for gas, they recommend, irrespective of whatever action, might they propose to lose no time in putting the matter to a practical issue. They notify their intention of opposing all the various applications of different companies, and of placing the matter under Parliamentary control as early as possible. It is proposed that the Town Council should themselves experiments being carried out without loss of time, and on such a scale as to yield complete results from one or two central stations. The Gas Committee conclude their report with the following recommendations:

1. That no application be now made by the council for authority to supply electricity in the borough or in any part of the district of their gas supply, either by license or provisional order under the Electric Lighting Act, or by special Act of Parliament. 2. That the committee be authorised to enter into negotiations with the companies applying for powers to supply electricity within the borough for the purpose of obtaining the license or order sufficient provision for storing in tion by the council of the full control of the streets for subsidiary of suitable sites for the works, for the safety of the public, for insuring the completion of the works within a limited time, and for the limitation of the term of the concession. 3. That, subject to satisfactory conditions being arranged with the companies in this way, the committee be authorised to support on behalf of the council, applications to the Board of Trade by one or more of the companies for power to supply one or more limited areas within the borough. 4. That, subject to the foregoing recommendations, the committee be authorised to oppose all or any of the applications of which notice has been given to the council.

Some time ago (see ENGINEERING, November 11, 1881) we published a detailed description of the process of protecting conductors, carried out by MM. Berthoud, Borel, and Co., of Paris. Since that date the manufacture of these cables in England has passed into the hands of the Electrical Trailing Company, 3, Victoria Mansions, Westminster, as will be remembered, MM. Berthoud and Borel employ as "an insulating material, cotton treated with paraffin and colophane, the wire previously encased in cotton sheathing being passed through a bath of the above mixture at a temperature of 350 deg. From this bath the conductor is passed through suitable dies, and by hydraulic pressure a sheathing of lead is forced around it. A considerable thickness of this sheathing, which is made in great variety of types, has been employed for electric lighting with good results. The conductors vary in weight from 95*l*. lb. to nearly 3 tons a mile, including outer sheathing of lead, which is preferably tinned, laced to protect the solid sheathing. The following are the particulars of a cable which is one of those manufactured:—A telephonic cable with four conductors, each formed of three wires, 23 B.W.G., covered with three layers of fine cotton and insulated with the Berthoud and Borel compound. The thickness of the insulated wire was .043 in. and the length of the cable tested was 6.20 kils. (3834 ft.)

Temperature.		Resistance of Dielectric per Kilometre.	Electrostatic Capacity per Kilometre.
Cent.	Fahr.		
deg.	deg.	megohms.	microfarads.
0	32	4000	0.185

51	123.8	450	0.199
54	129.4	310	0.122

The resistances and capacities were determined in each case after one minute of electrification.

The large and very fine machine, the Gordon dynamo-electric generator, the design of which has occupied Mr. Gordon for a considerable time, is now in operation at the Telegraph Construction and Maintenance Company's Works, East Greenwich. The aim of the inventor has been to provide a generator of a size and power sufficient to supply from five to ten thousand incandescent lamps; being persuaded that such large machines are necessary in order to the more economical production of the electric light. It is constructed on the plan of revolving the electro-magnets and keeping the armature coils fixed. We shall publish next week a full and illustrated description of the machine, which contains many novel and ingenious features. On Wednesday evening the new generator was publicly exhibited by Mr. Gordon and Mr. R. Clapham, to a number of gentlemen interested in electric lighting; and the works of the Telegraph Construction and Maintenance Company were illuminated throughout by 1200 Swan lamps, maintained by it while working at a fraction of its full power.

The contract which the British Electric Light Company have had for the lighting of St. Enoch Station, Glasgow, for the past three or four years, is to come to a termination at the end of this month. All along there have been in use six powerful arc lights. For a considerable time the reception lamps were employed, but lately they were replaced by Brockie lamps, which have certainly never been a complete success. That may in some degree have been owing to the fact that the engine used to drive the dynamos is the one whose duty includes the working of the laundry belonging to the Station Hotel, so that the lights could not be always kept going at full pace. It is intended to continue the use of the electric light in the station, the new contract having already been placed with Messrs. Norman and Son, of Glasgow and Barrow-in-Furness; but as the dynamos have been arrived at very recently, it is possible that the new installation may not be completed for three or four weeks, in which case, not unlikely, the old gas will have again to be resorted to for a time. It is understood that Messrs. Norman and Son will employ in their installation four Crompton arc lamps of the most recent form, and numerous clusters of incandescent lamps. Messrs. Norman and Son have lately secured extensive premises in Argyll-street, Glasgow, in which several varieties of the Swan incandescent lamps will shortly be permanently installed. Already the firm have laid down on their premises three Crompton-Burgin dynamos, and a semi-portable compound engine, of 14 horse power, by Marshall and Co.

Messrs. Henry Bennett and Co., electric light engineers, Glasgow, have just started a very complete system of arc lighting at the works of Messrs. Gosselin and Co., tinsmiths, &c., and steel engravers, &c., Motherwell, which is the first electric light installation in the district. There are four Crompton lights in the installation, one of which is a semi-final light in the yard placed at a height of about 60 ft. from the ground, while the other three are placed in line in the spacious globe buildings shop. The power is obtained from an engine by Shanks, of Arbroath, and the lighting current is generated by a Crompton-Burgin dynamo machine running at a rate of 1,000 revolutions per minute. In consequence of the necessity of the travelling crane in this shop, the engines, machinery, lighting, and dynamo are fixed on a platform which is built on the tie beams of the roof of this building, and from the platform there is a gear for running the travelling crane. The gear for the purpose of readily getting at the individual lamps, in the event of any lamp becoming extinguished from the arcs having a similar installation to the one just referred to, has been fitted up somewhere on the Forth and Clyde Canal, near Glasgow, where Messrs. Morrison and Mason, engineers, are engaged in making a deviation of the canal. A portable engine by Brown and May is used to supply the power. Messrs. Watt and Wilson, contractors, Glasgow, are having fitted up by the same firm an electric lighting arrangement of a similar character at the railway lodges which they are constructing over the Forth and Allan. The light in this case is to be chiefly used by night in the sinking of the foundations, for which the piers are to be carried. A portable engine is also to be used in this installation for obtaining the necessary power.

On the motion of Lord Provost Ure, seconded by the predecessor in office, Sir William Collins, the Glasgow Corporation Gas Commission have obtained an applying forthwith to the Board of Trade for a provisional order to supply electricity within the burgh of Glasgow, under the Electricity Clauses of the Electric Lighting Act of 1882. The electric light has for several miles around the city are almost wholly supplied entirely by Glasgow Corporation Gas Commissioners, but the resolution which has just been passed is the first step which has been taken to go beyond the municipal boundaries in the matter of supply of the electric light; indeed, one of the resolutions passed when speaking upon the Lord Provost's motion did not hesitate to make the absurd statement that any one who thought of supplying electricity within the burgh understand that it could not be extended beyond half a mile from any one gas generating station.

MM. Egasse, Mangin, and Cloris-Baudet, of Paris, have recently introduced some interesting apparatus having for their object the development of a system of slight signalling by means of small captive balloons, to which are attached incandescent lamps. The balloon experimented upon was of 10 cubic metres capacity, and made of transparent impermeable rubber fitted with hydrogen. The lamps are suspended from the balloon by a Swan lamp. The balloon was allowed to ascend, and when the air the current was passed through the lamp, the effect being to illuminate the paper sphere to such an extent as to allow it to be visible for a very considerable distance. By suitable manœuvres a very perfect system of Morse signalling may be established, and messages transmitted at night with great facility. The great merit and real value of the arrangement must lies in the illumination by one or more incandescent lamps of a sphere large enough to be seen through considerable distances.

The French Minister of Marine has appointed a commission to investigate and report upon a new arrangement for illuminating submarine operations. A powerful arc lamp is enclosed in a water-tight case, the bottom of which is formed of a glass disc, and the case is provided with a reflector that will distribute the light over a circle about 197 ft. in diameter. The series of experiments, which it is intended shall be very complete, will be conducted at Marseilles. The divers will be in telephonic connection with the surface, and be able to direct the movements of the lamp, which will be suspended over the operations, and can be shifted at will.

A successful installation on the Solvit system has been made at Antwerp, where a 10-horse power portable engine is employed to drive a Type II. Gramme machine with separate exciter. This generator feeds two circuits, on each of which are six Solvit lamps; of these, one is placed in the first-class waiting-room of the Antwerp Railway station, six are in as adjoining café, four in a second café, and one is in the machine-room of the installation. The lamps have been running about six weeks and have given great satisfaction. During that time application for sixty more lights has been received by the company, who will probably extend their power station as soon as possible.

Engineering, Oct 20, 1882.

ELECTRIC LIGHTING.

A VERY important experiment is now being carried out at the Gare de l'Est, Paris, which will unite the station buildings in Paris and the whole of the line between that terminus and the Villette station, the railroad for that length being either in tunnel or between retaining walls. An important feature in this section are the traverse tables introduced for shifting carriages from one line to another, to facilitate the trestle, and the gas illumination for this purpose has always been found insufficient. The new installation is being carried out by the Société Lyonnaise des eaux et de l'Eclairage, and will comprise fifteen large arc lamps. Of these will be placed in the Partsistation, three will be on the goods depôt, and the others in the station yard. As the system will be employed, the generators being of the Gramme type, will be driven by a 15 horse power Weyher and Richemond engine at a speed of 340 revolutions per minute. The current will be of the double type, with certain 11 millimetres in diameter. The length of the exterior circuit is 4700 metres, the resistance of the circuit being 15 ohms. The intensity of the current feeding the lamps is from 10 to 10.5 ampères. The following photometric tests have been made with one of the lamps, the "Starr" candle and the Carcel standard having been used.

1. With *Standard Candle*:

Incidence of Rays	Nature of Light.	Luminous Intensity.	
90 deg.	Naked arc	444 candles	22 carcels
80 "	"	500 "	=101 "
70 "	In ground glass globe	277 "	= 57 "

2. With *Carcel Standard*:

0 deg.	In ground glass globe	49 Carcels	
10 "	"	66 "	
20 "	Naked "	79 "	
30 "	"	114 "	
50 "	"	101 "	
70 "	"	65 "	

These results, which appear to have been carefully obtained, do not agree with the more liberal allowance of luminous intensity usually accorded to this lamp.

Under the title of *Souvenirs de l'Exposition Internationale d'Electricité de Paris*, 1881, our excellent contemporary, *La Lumière Electrique*, has just issued a handsome volume, containing the admirable series of articles which on the first great electrical exhibition has been so fully devoted. The issue in question contains a number of finely executed engravings of the Palais de l'Industrie, comprising views of the exterior and interior; it is to be hoped that the report of the Exhibition published in our contemporary will be collected and published in a separate form.

In Germany, on the Frankfort and Fulda Railway, some interesting experiments are in progress on lighting trains with incandescence lamps. The experimental train consists of two first and second-class carriages, a saloon, a fourth-class carriage, and a brake van, in which latter is placed a Wilson dynamo-electric generator, and forty-four cells of accumulators, eleven of which are held in reserve. These are distributed through the train twenty-three Edison lamps. The generator is driven off one of the axles of the brake van, and being a dog lamp when the train is in motion, the current being taken from the accumulators, when it stops. So far the experiments have been encouraging, but they have developed a number of practical difficulties which will have to be overcome before the installation is successful.

Mr. James Gordon Bennett's yacht, the Namouna, now on a tour round the world, recently visited the Port of London. She is lighted throughout by 150 Edison incandescence lamps, fed by a 50 horse power generator, driven by belting from a special engine. On her way from New York she was exposed to very heavy weather, but no interruption to the lighting occurred, nor was there any instance of the belt slipping. This experience is a valuable one, and will probably serve to remove the distrust in belting for driving dynamos on board ship, where direct driving is generally preferred.

The steamships Tarawera and Waiilkore, now being built by Messrs. Denny and Co. for the Union Steamship Company, of New Zealand, will each be fitted with 150 Edison 16-candle lamps, fed by an Edison dynamo, driven direct by a Beckenbaud three-cylinder engine.

A meeting has been convened by the Vestry of Camberwell of the various South London vestries, to decide upon the most expedient action that should be taken in regard to the numerous notifications made by different electric light companies, of their intention to apply for provisional orders to empower them to distribute electricity throughout the South London parishes. The meeting will take place on Tuesday the 31st inst. It is intended that the vestries will arrive at some course of joint action which shall as far as possible protect the interests of the ratepayers.

The Wandsworth District Board of Works next Thursday week, by a majority but, agreed to the following recommendation of their General Purposes Committee: "The General Purposes Committee have considered the applications for the consent of the Board to Board of Trade licences or provisional orders being granted for the supply of electricity within the district, received from the following companies:—1. The Metropolitan Electric, the Gallery, Victoria Chambers, and the West Middlesex, and Messrs. Byrne and Thomson, and Isca; and recommend that the Board do not grant their consent to any of the proposed schemes. 2. That the applicants and the Board of Trade be informed accordingly; and that the Board of Trade be further informed that the Board have it in contemplation to apply for a license themselves for the supply of electricity in the district when the system of electric light is more matured.

The Sanitary Committee of the Bristol Town Council, acting as the Urban Sanitary Authority, have issued a circular recommending the council to apply to the Board of Trade for a provisional order for powers to establish electric lighting installations in the city of Bristol.

Engineering, Oct 20, 1882.

THE MUNICH ELECTRICAL EXHIBITION.

In less than four years, four electrical exhibitions have been held, and in most cases are in preparation to satisfy the overpowering demand for novelty so universally exacting. The first exhibition of this class was held at the Royal Albert Hall in 1879; its proportions were very modest compared to those which so rapidly succeeded it, but it formed a useful commencement to the labours of the Society, whereby but, agreed to the following recommendation of their General Purposes Committee: "The General Purposes Committee have considered the applications for the consent of the Board to Board of Trade licences or provisional orders being granted for the supply of electricity within the district, received from the following companies:—1. The Metropolitan Electric, the Gallery, Victoria Chambers, and the West Middlesex, and Messrs. Byrne and Thomson, and Isca; and recommend that the Board do not grant their consent to any of the proposed schemes. 2. ELECTRO LIGHTING.

We obtain from various sources the following current notes referring to electric lighting. A special report of the directors of theatres in Germany has been formed to inquire into the question of electrically lighting theatres. This commission is pursuing its inquiries experimentally in the Electrical Exhibition now being held at Munich; for this purpose a theatre has been arranged, the upper part of the amphitheatre of which is now lighted with six Krizik lamps, while groups of Edison lamps are ranged round the walls. The stage is illuminated partly with Jaublochkoffs, partly with arc-lamps, the combination of which is found to be successful; experiments are here being made with effects produced by enclosing the lamps in Celestin lanterns.

The following are some notes of the Schultz (Strasbourg) secondary batteries shown at Munich. The lead plates composing the battery are grooved longitudinally and covered with sulphur; under the influence of heat sulphate of lead is formed. Several such plates, mounted parallel, are plunged in a lead-lined wooden trough containing dilute sulphuric acid. Each cell weighs about 17 lb., and according to the inventor can receive about 1,000 to 1,200,000 foot-pounds. It is stated that the batteries are easily "formed," an exposure to a current of four amperes during forty hours being sufficient for this purpose. The resistance of each cell when charged is .005 ohm, when not charged, .012 ohm. It is stated that these batteries have a very effective odour.

It is proposed to light the Munich Stadt-am Rosen to facilities for illumination during the Carnival.

The lead plates composing the battery are grooved longitudinally and covered with sulphur; under the influence of heat sulphate of lead is formed. Several such plates, mounted parallel, are plunged in a lead-lined wooden trough containing dilute sulphuric acid. Each cell weighs about 17 lb., and according to the inventor can receive about 1,000 to 1,200,000 foot-pounds. It is stated that these batteries are easily "formed," an exposure to a current of four amperes during forty hours being sufficient for this purpose. The resistance of each cell when charged is .005 ohm, when not charged, .012 ohm. It is stated that these batteries have a very effective odour.

It is proposed to light the Munich Stadt-am Rosen to facilities for illumination during the Carnival. A railway station of the Isar-Loisach line is erected in one night, by the aid of four electric lamps enclosed in globes of different colours; a considerable amount of heavy earthwork is also completed.

In Berlin, the Place Potsdam and the Leipzig Strasse are at present illuminated by means of Siemens and Halske dynamo machines; the power station six conductors are laid underground along the Dorotheen Strasse, from the Friedrich Strasse to the Spree and three to the Place Potsdam. These cables are laid in cast-iron pipes in the streets, and covered with tiles; where they cross, they are carried in iron pipes; the total length of the conductors is about 1,200 yards. Two large Siemens machines illuminate the Place Potsdam, while 25 others are in use in the Friedrich Strasse. The machines are driven by gas engines. The installation is experimental, and the time of lighting is from sunset to midnight.

The Vendôme Hotel at Boston has recently been lighted with the Maxim lamps, and the Parliament Building at the Parliament Building at Capetown, constructed in London, appears to be giving excellent satisfaction. This installation comprises 44 lamps, 24 in the Assembly Hall and 20 in the gallery.

At Waterloo House, Pall Mall, has just been lighted by the Anglo-American (Brush) Electric Light Company; the installation consists of 16 arc lamps, and the power is a 12 horse-power Otto gas engine.

On Tuesday last, at a meeting of the Anglo-Austrian Brush Electric Company, it was stated by the chairman (Sir William Stephenson), it appears that the public had been very anxious to take up the company, 32,038 shares having been taken up. The company had realized its demands and had received 27,000*l.* in cash, and the balance (75,000*l.*) in shares. The property of the company consists of the Brush and Lane-Fox patents for Austria and Hungary, and in relation to the Lane-Fox patents it was pointed out that one was especially valuable, as it claimed that an system of dynamos, accumulators, and incandescent lamps could be used together except under a license from Mr. Lane-Fox, who has patented the combination. This claim may probably open up a wide field for litigation in the future. The company appears to have a position in Austria and Hungary by this company, though it is stated that many important contracts are soon to be entered into.

At a meeting of the City Commissioners of Sewers on Tuesday last, a report was presented by the Streets Committee on the various notices from the Electric Lighting Companies, of their intention to apply for provisional orders under the Electric Lighting Act of the present year; this report recommended that the Commissioners of Sewers' solicitor should report on the applications, and secure clauses protecting public and private rights.

The Vestry of the parish of St. George the Martyr, Southwark, are preparing to take active measures in regard to electric lighting. A meeting of the Board was held on Thursday evening last, at which it was resolved to oppose the application of electric lighting companies for powers under the Act, unless they are prepared to give a guarantee to divide all profits with the vestry, after allowing their shareholders a dividend of 7*l.* per cent. The object of this resolution is to reduce the local rates. This appears a very reasonable determination, and one which the companies will doubtless accept; it is doubtful, however, whether any appreciable reduction in the rates will be effected by this means for some time to come.

The Sheffield Corporation are proposing to apply for electric power powers under the Act during the coming year, the intention being to commence the lighting of the town in the streets and public buildings, as well as in private houses. Such an undertaking will be a very onerous one, and the Corporation consulted yesterday with the representatives of some of the principal electric lighting companies upon the best system to be employed. Mr. Colpell W. Cooke is acting as consulting engineer to the Corporation.

The experiment of lighting by electricity at Chesterfield has not so far proved successful. It will be remembered that about a year ago, owing to differences with the gas company, the Corporation determined to abandon gas for street lighting, and to illuminate all the streets with arc lamps. A contract was entered into by the Improved Company, and it was decided to use both arc and incandescence lamps. There is no doubt by the work has recently been handed over by the contractors as complete, but according to the Town Council it is little less than a climax before. It is better addressed to the papers yesterday. Alderman Gee says: "The Lane-Fox lamps which have been supplied by the Brush Company are most valuable in their lighting power, cheaper some are good, others only give a feeble light instead of a light equal to that of fifteen candles as expected. The Brush lamps have been good service of the large streets, but as a whole I think it has been fully demonstrated to the people of Chesterfield, that the field for arc lighting is very limited indeed." The inhabitants of the town are very much inclined in any other instance to condemn the system and the disappointment at the result of the misleading experiments is very general. Judging from the success that has attended the electric lighting of towns where we suspect that the fault has been with the mode of installation; the defective Lane-Fox lamps should be replaced by perfect ones and the system of a better distribution of the arc lights could be effected; many towns have been in a timely way to adopt an economical bodies are turning their attention actively to the question of abandoning gas.

The Town Council of Aberdeen, who have received notices from four or five companies having powers under the Act of their intention to apply for licenses to the Board of Trade to supply electric light to the town, have decided to protect the interests of the ratepayers and the owners of the town gas works, and to prevent any one company from obtaining an exclusive footing.

Progress in electric lighting is being made in Scotland to a variety of directions. Although not much that may result through the applications to Parliament for powers to take breath of fresh air. Already a year ago a local company was formed in Dundee under the name of the Dundee Electric Light, Power, and Accumulator Company, with the intention of supplying electric light and power by any apparatus that might be used, approved of; and it was stated that extensive installations are in process of being carried out by that company in Dundee and the neighbouring districts. Besides numerous exhibitions of incandescence installations of arc lamps, ranging from three to twelve lamps each, have been taken up by the Edinburgh, Glasgow, Dundee, and Bellshill Co-operative Societies, the installation of the 100 incandescent lamps, each lamp, completed in another Forfar factory, which one of our

Coventry, 13.1.82

ELECTRIC LIGHTING.

We obtain from various sources the following current notes relating to electric lighting. A special commission of the directors of industries in Germany has been formed to study the question of electrically lighting theatres; this commission is composed of twenty-four functionaries at the Electrical Exhibition now being held at Munich. For this purpose a theatre has been arranged, the upper part of the amphitheatre of which is now lighted with six Krizik lamps, while the lower part of the lamps are ranged round the walls. The stage is illuminated partly with incandescence, partly with arc lamps. The combination of which existed not to be successful; experiments are being made with effects produced by covering the lamps in Coloured lanterns.

The following are some notes of the Schnitz (Styria) lacery) electric lighting factories shown at Munich. The plates consisting the battery are grooved longitudinally and covered with sulphur; under the influence of heat a sulphate of lead is formed. Several such plates, mounted parallel, are placed in a lead-lined wooden box, and contain 17 lb., and accordingly the inventor can receive a charge equal to 250,000 foot-pounds. It is stated that these batteries are easily "formed," an operation to correct this purpose. The resistance of each cell when charged is 1600 ohm, when not charged, 312 ohm. It is stated that these batteries have a very effective use.

It is proposed by the Municipal Council at Rouen to utilise the Seine as a source of power to drive machinery for lighting the city, and the matter is now being technically investigated. The power stations would be at Pont de Pilmes, and dynamo engines would be laid throughout Rouen and Elbeuf. Gas lighting in the latter city would be discontinued, and a number of the spire of the cathedral, at a height of nearly 500 ft., powerful arc lamps, the light from which would be thrown over the streets by reflectors.

The military authorities at Belfort have been entrusted with the lighting by oil of the electric light. At Schneeberg arc lamps have been used, and recently there has been erected in the same manner. A railway viaduct about 130 yards long has also been lighted by arc lamps, with the aid of four electric lamps enclosed in globes of different colours; a considerable amount of heavy cannon can be seen from the viaduct.

In Berlin, the Place Potsdam and the Leipzig Strasse are lighted by the Siemens lamps, and the Leipzig Strasse partially. From the power stations arc conductors are laid underground along the Guillaume Strasse, thence going to the Frederic Strasse, and three to the Place Potsdam, and from these the lamps are hung along the streets, and covered with tiles; where they cross, they are suspended by cables. The length of arc conductors is about two miles. Ten large Siemens lamps illuminate the Leipzig Strasse, and are recently been lighted at the Parliament Building, and also the Edison installed in May last, appears to be giving much satisfaction. This installation comprises 400 lamps.

The Vienna Electrical Society has recently been lighted with 60 Edison lamps, and the Edison installation at the Parliament Building, Budapest, was installed in May last, appears to be giving much satisfaction. This installation comprises 400 lamps.

Waterloo House, Pall Mall, has just been lighted by the Metropolitan (Brush) Electric Light Company; the installation consists of 16 arc lamps, and the power is 12 horse-power gas engine.

On Tuesday last the general meeting of the Anglo-Austrian Brush Electrical Company was held, and across rather interesting statements were made by the chairman (Sir William Siemens), who said that since the public had submitted very actively to this company, 10,000 shares having been taken up. The vendor had reduced his demands and had accepted £70,000, and had also taken £30,000 in shares. The property of the company consists of the Brush patents for Austria and Hungary, and also of the Lane-Fox patents in reference to the Lane-Fox patents it was pointed out that one was especially valuable, as it claimed the entire system of dynamos, accumulators, and incandescent lamps could be used together except under a license from Mr. Lane-Fox, who has patented the combination. This claim may probably open up a wide field for litigation in the future. No business appears to have been done in Austria and Hungary by this company, though it is stated that many important contracts are soon to be closed.

At a meeting of the City Commissioners of Sewers on Tuesday last, a report was presented by the Streets Committee as to the various notices from different Electric Lighting Companies, of their intention to apply for provisional orders under the Electric Lighting Act of the present year; this report recommended that the Commissioners should oppose all similar schemes, and appointed a sub-committee to consider the matter and report on the private rights.

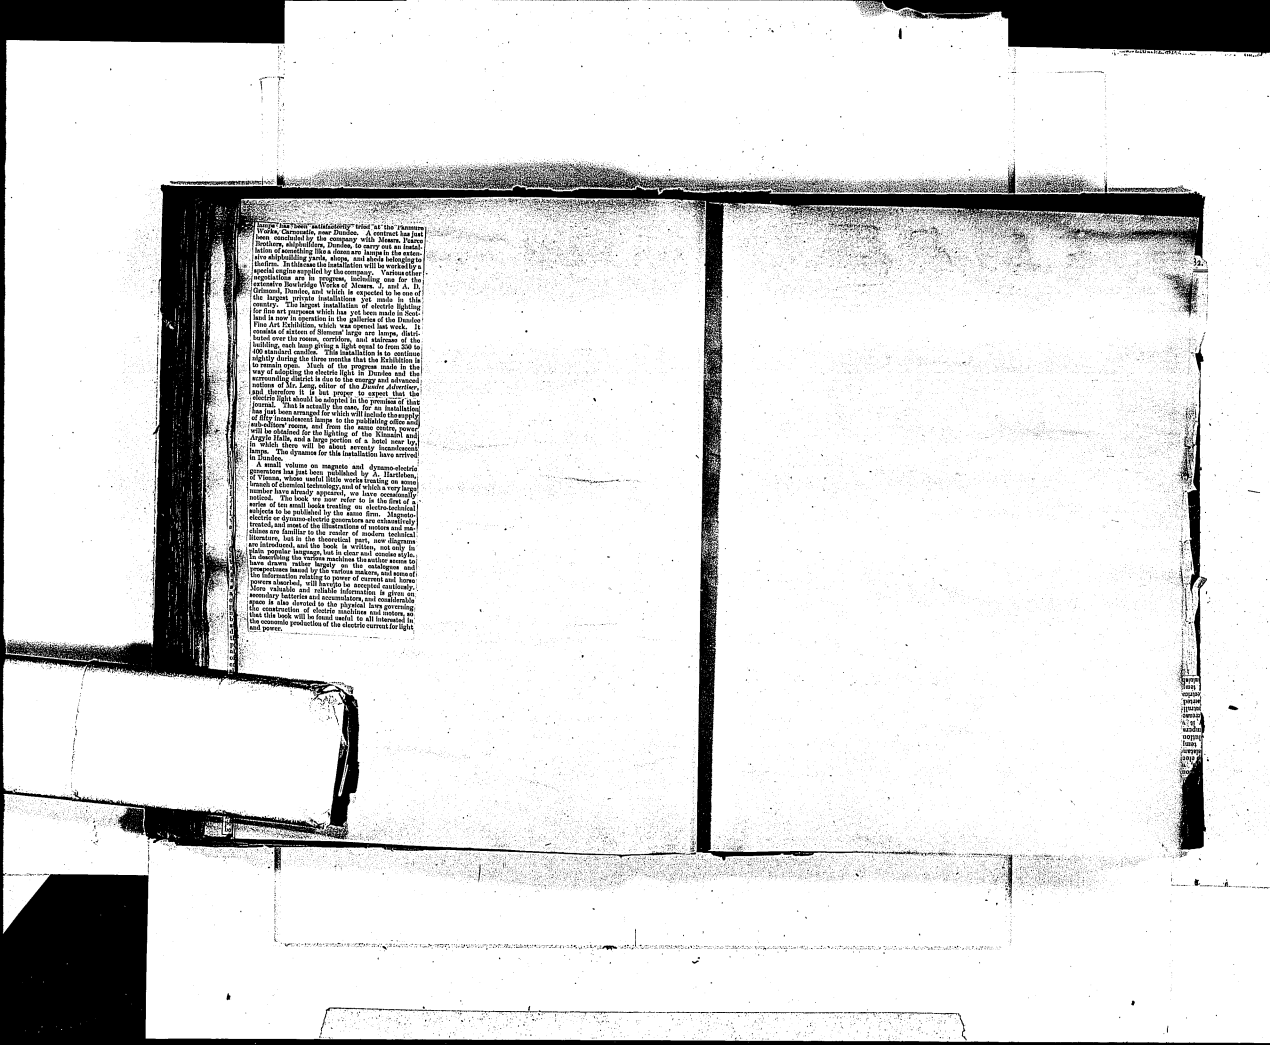
The vestry of the parish of St. George the Martyr, Southwark, are preparing to take active measures in regard to electric lighting. A meeting of the Board was held on Tuesday evening last, when it was resolved to oppose the application of electric lighting companies for powers under the Act, unless they are prepared to give a guarantee to divide all profits to the vestry, after paying their shareholders a dividend of 7 per cent. The object of this resolution is to reduce the local rates. This appears a very reasonable recommendation, and one which the company will doubtless accept; it is doubtful, however, whether any appreciable reduction in the rates will be effected by this means for some time to come.

The Sheffield Corporation are proposing to apply for extensive powers under the Act during the coming session, the intention being to supersede the lighting of the town, in the streets and public buildings, as well as in private houses. Such an undertaking will be a very serious one, and the Corporation consulted yesterday with the representatives of some of the leading electric lighting companies upon the best system to be employed. Mr. Conrad W. Cooke is acting as consulting engineer to the Corporation.

The experiment of lighting by electricity at Chesterfield has proved as far proved successful. It will be remembered that about a year ago, owing to differences with the gas company the question arose whether to continue to illuminate gas for street lighting, and to illuminate all the streets with gas lamps. The contract was entrusted to the Thomson-Houston Company, and it was decided to use both arc and incandescent lamps. After a long delay the work has recently been handed over by the contractors as complete, but owing to the Town Council it is little less than a disappointment. In a letter addressed to the papers yesterday, Alderman Cox says, "The Lane-Fox lamps which are now supplied by the Brush Company are most variable in their lighting power, whilst some are good, others only give a feeble light instead of a light equal to that of eight candles as expected. The arc lights are also giving bad service in some of the large streets, but as a whole the lighting has not been fairly demonstrated in a year's trial in Chesterfield, that the field for arc lighting is very limited indeed." The disinclination of the Council to appear inclined to any single instance to abandon gas, and the disappointment which many of this recent lighting experiment is very natural, judging from the success that has attended the electric lighting of towns elsewhere we suspect that the real cause lies chiefly with the mode of installation; the defective Lane-Fox lamps can scarcely be replaced by perfect ones, and probably a better distribution of the arc lights could be effected. Alderman Cox's letter is hardly one, now that so many municipal bodies are turning their attention seriously to the question of electric lighting.

The Town Council of Newbury, who have received offers from four or five electric lighting companies of their intention to apply for licenses from the Board of Trade to supply electric light to the town, are now taking steps to protect the interests of the Corporation as owners of the gas works, and to prevent any company obtaining a monopolistic footing.

Progress in electric lighting is being made in Scotland in a variety of directions, almost as great from anything that may result through the application of various municipal bodies to take Board of Trade licenses. About a year ago a local company was formed in Dundee under the name of we mistake not, of the Northern Electric Light, Power, and Application Company, with the intention of supplying electric light and power by any apparatus that might be most approved of; and it is now stated that extensive installations are in process of being carried out by that company in Dundee and the surrounding district. Numerous exhibitions of a temporary nature, installations of not large, ranging from three to eight lamps each, have been made in large factories in Perfar, Blairgowrie, Dundee, Bellshill, and an installation of 100 to 120 incandescent lamps has just been completed in another Perfar town, while one of are



THE ELECTRIC LIGHT PLANT ON THE S.S. "OREGON."

(For Description, see Page 336).

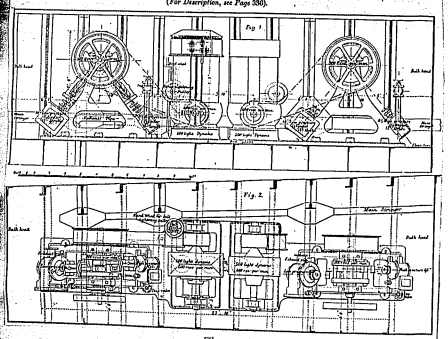


Fig. 1.

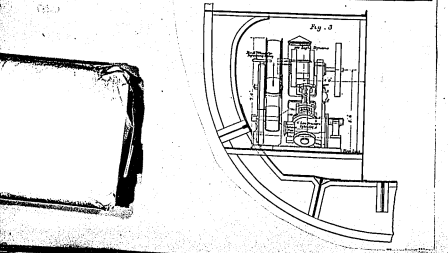

Fig. 2.

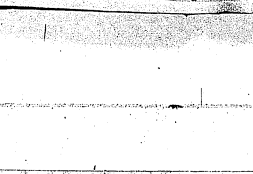

Fig. 3.

THE ELECTRIC LIGHTING OF THE S.S. "OREGON."

On page 332 will be found illustrations of the electric light plant recited by the Edison Company on the s.s. Oregon, the new ship of the Guion line, which has been built to out-run the famous Alaska. The machinery consists of ten Edison-Hopkinson dynamos, constructed by Messrs. Mather and Platt, of Salford, each of them capable of maintaining 800 incandescence lamps, or a little more than the total number (600) included in the installation, which is the largest yet erected on board ship. They are intended to run at 600 revolutions per minute and generate a current with an electromotive force of 110 volts. The two machines are erected face to face, and each is provided with a separate engine, so that the whole of the generating plant is in duplicate, affording a guarantee against stoppages from breakdown. The engine power is transmitted through belts which run under tightening pulleys carried in slides along which they can be moved by screws as the straps become slack.

The engines are of Messrs. Mather and Platt's compound diagonal type, with cylinders 8½ in. and 14 in. in diameter respectively, and are fitted with Arnold, Ten and Sinn's governors and valve gear. The slide valve consists of two pistons without rings, connected together by a hollow cylinder. Each piston serves as a short cylinder open at one end to the steam chest, and at the other to the exhaust pipe, and having at its centre a port leading to the end of the main slide cylinder. Each of the pistons of the valve has a port formed in it, in connexion with the hollow cylinder, and consequently, with each other, and these are so arranged that when the edge of the piston moves over the edge of a cylinder port to admit steam, a second supply of steam enters through a port in the opposite piston valve, passes through the connecting cylinder, and through the other valve port into the cylinder port. By this means steam is taken very nearly to the end of the movement of the stroke, and there is no dead centre. The automatic cut-off is effected by a governor mounted on the crankshaft, and acting directly on the eccentric. The engines run at 300 revolutions per minute.

ELECTRIC LIGHTING NOTES.

The Electric Lighting Contract and Maintenance Company, (in liquidation) held its final meeting on October 1. There have been two dividends paid to the shareholders, leaving a balance in hand of £1,000. It turned the whole of the subscribed capital, from £4 per cent., and backing to the quoted prices of many of the electrical companies' shares there seems little doubt that the shareholders must in consequence experience a feeling of gratitude towards their directors. The company was floated with the avowed object of furnishing electricity in the same way that gas companies distribute gas, and for many months it spared no pains in seeking for contracts or for a suitable site for the establishment of a central station, but after it became apparent that there was no remunerative field for this kind of business the directors advised voluntary winding-up. Of course they received numerous offers of the sale of patents, but under the advice of their engineer they wisely refused them all, and consequently their assets have returned nineteen shillings in the pound, which is probably more than they would have done if they had imbibed any grants of patent rights for electric lamps or dynamos.

The Edison electric light has been installed on board the fine new passenger steamer Paterna, built and engined by Messrs. A. and J. Inglis, Glasgow, for the Tasmanian Steam Navigation Company, of Hobart Town. The construction of the vessel was carried out under the supervision of Mr. H. R. Bellamy, who placed the electric lighting under the direction of Professor Jamieson, F.R.S.E., of the College of Science, Glasgow, who drew up the specifications and inspected and tested the work. The steam dynamo, of 3 type, is driven by a patent Westinghouse engine made by Messrs. Alley and M'Lellan, engineers, Glasgow. The peculiarity of this engine is that there are two single-acting inverted cylinders with steam and coupled direct to the connecting rods of the whole of the working parts below the cylinder bottoms, placed in an oil-tight tank with a very complete and perfect system of lubrication. The strokes is extremely short, the engine occupies very little space, and runs with great steadiness, freedom, and economy of steam at from 300 to 700 revolutions per minute, a speed which for several reasons, is as high as is advisable to employ for dynamos on board ship. The engine shaft is extended and connected direct to the dynamo spindles, thus doing away with all friction gearing or belting. The total space occupied by the engine and dynamo measures 7 ft. 6 in. from fore and aft by 3 ft. 6 in. athwart, and 4 ft. 6 in. high; they are placed on the same floor as the main engines so as to be under the supervision of the engine-room watch. The switches regulating the various circuits of the ship, such as saloon, cabins, engine-room, &c., are all placed close to the dynamo in a handy position. The main conductors are strands of seven No. 16 copper wire, made by the India-Rubber and Gutta Percha Company, and have telegraph insulation equal to 100 megohms per 1000 yards at 60 deg. Fahr. The leads throughout the whole ship have been kept apart by grooved wooden scantlings. There are 160 lamps in all; those on the saloon are hung independently from the sides of main oil lamp pendant chandeliers, 12 round-glass globes are employed, and the metal work is of artistic design. There are several other installations of the kind in progress in Glasgow.

Engineering, April, 1882.

STEAM ENGINES AND THE ELECTRIC LIGHT.

Answer the numerous side issues more or less connected with the successful introduction of electric lighting on a large scale, there is one which has not yet, we think, met with the attention it merits, although its importance is beginning to be felt by those actively engaged in the establishment of electric lighting installations. We allude to the provision of the motive power required. During the past year or so numerous companies have been formed for the purpose of introducing this or that system of electric illumination, and there have been subscribed large amounts of capital, portions of which it has been proposed to expend in laying down plant for the construction of dynamo-machines, lamps, &c. It appears, however, to have been very generally assumed that whatever the extent to which the introduction of the electric light developed, there would be no difficulty in obtaining the necessary motors, or in other words, it seems to have been taken for granted that our steam engine builders would at once be able to increase their output to meet any increased demand. That electric lighting tended to spread as rapidly as some of the sanguine promoters wished the public to believe, we venture to say, that before now matters would have been brought to a dead lock by the sheer impossibility of fitting up the power stations, while even as it is the introduction of electric lighting has had a very important effect on the market for stationary engines.

It is to be borne in mind that engines for driving electric light machinery have to satisfy special conditions. To give satisfaction they must possess sufficient power so as to obtain the greatest possible uniformity of speed under greatly varying loads, they must be capable of running a large number of consecutive hours without stopping for refitting, &c., and they must be economical steam users. Now while we have in this country a very large number of steam engine builders, the number of firms whose plants fulfil the above conditions is comparatively limited, and they are, moreover, most of them makers whose ordinary business consists in doing their manufacturing plant pretty fully employed. It is not surprising therefore that the demand of an entirely new source of demand like that which has now sprung up should have a material effect on the higher class of steam engine makers, and that if should at the present time be difficult to procure engines thoroughly suitable for electric lighting for any thing like prompt delivery.

So far most of the electric light installations which have been carried out have been on a very modest scale, but comparatively few necessitating the provision of 100 horse-power, and the majority of them being considerably less. If, however, the electric light is to take in the future anything like the position which there is at present every reason for supposing it will occupy, matters will be very different, engines developing many thousands of horse-powers will be required in our large towns. A few general figures may suffice to show more clearly how the matter stands.

We have not at command particulars of the total gas production in London during the past year, but in 1880 it reached about 1,700,000,000 cubic feet, and judging from the rate of increase in late years, the natural growth of the population, and the demands for improved lighting, it will certainly not be less than the round figure of 2,000,000,000 of cubic feet annually. The rate at which the consumption goes on naturally varies greatly at different periods of the day and of the year, but we shall probably be erring on the side of liberality if we assume that the hourly consumption frequently reaches one two-thousandth of the annual consumption, or say 10,000,000 cubic feet per hour. But one million cubic feet per hour will supply 200,000 of Edison's flat flame burners, giving a light equal to fifteen hundred candles each, while in ordinary practice this quantity of gas is probably on the average distributed between a considerably larger number of burners of less illuminating power. Let us, however, suppose that 200,000 burners are replaced by say 200,000 incandescent lights, and let us further assume that it is possible to supply the necessary current to eight of these lights for each horse power developed—a favourable assumption—then it will be seen that there would be required no less than 25,000 horse power to drive the incandescent lights necessary to replace but about one-tenth of the gas consumption in the metropolitan district. Of course, if an effective system of storage batteries can be employed the maximum horse power required at any one time would be reduced, but, on the other hand, the above estimate includes no allowance for the spare engines which must necessarily form part of a permanent electric lighting establishment. To replace about ten per cent. of the present gas lights in London alone by incandescent electric lights, would thus involve the expenditure on engines and boilers of about a quarter of a million sterling, and when it is considered how comparatively few are the firms by whom the necessary high class engines of large power can at present be turned out, it will be seen that the introduction of the electric light on a very large scale must necessarily take place very gradually even from this cause alone.

We have above stated some of the requirements of engines for driving electric light machinery, and we may point out here that the ultimate design which it will be found best to adopt for such engines will be materially affected by the question of whether or not storage batteries can be successfully employed on a large scale. If they can, the steam engines of electric light stations will be brought into the same category as pumping engines; it will be possible to keep them continuously at work, and except perhaps in a few districts where fuel is exceptionally cheap—it will be desirable to adopt very refined means for economy of fuel. On the other hand if storage batteries are not employed it will be necessary that the engines will be employed for but a very few hours daily, and the designer will be obliged to adopt types of engine even at the expense of a greater consumption of fuel. Altogether the introduction of the electric light promises to have an important effect on the development of our production of stationary steam engines; the influence has already strongly felt by the makers of engines of the smaller powers, and it will probably not be very long before the manufacturers of engines of the larger sizes are called upon to meet the demands which will be made upon them.

Nov. 24, 1882.

ENGINEERING.

ELECTRIC LIGHTING NOTES.

It will be remembered that a short time since the Streets Committee of the City Commissioners of Sewers gave instructions that the opinion of some leading electrician should be obtained on the practicability of laying in the main tubes, the conductors of various companies for lighting by different systems without any interference with each other, and whether the conductors of one system would be available for those of another system. The committee requested Mr. H. Preece to report on the subject, and at a special meeting of the commissioners, held yesterday, the report was laid upon the table. Mr. Preece gave it as his opinion that it would be practicable to lay conductors of different systems in the same tube, unless it was in a subway of considerable size. Considerable space of conductors laid for one system, by a contractor to one leading another system, Mr. Preece says in his report that the proper arrangement of wires for an electric light system is a very complicated matter, and that this whole question of electric lighting is entirely in a tentative condition. Mr. Preece considers that the corporations who have undertaken themselves to supply electricity have assumed a responsibility the extent of which they are ignorant, and which they will find it very difficult to discharge. After the report was read at the meeting, Mr. J. V. Moore moved the resolution: "That the Remembrancer be instructed to take all necessary steps to enable the Commission to become the undertakers for the supply of electricity to the City under the provisions of the Electric Lighting Act of 1882, and to obtain a provisional order under the regulations laid down by the Board of Trade, and on the opposes the applications of all other parties." To this resolution the following amendment was proposed: "That while the Commission is in favour of electric lighting in the streets, they are not prepared to enter further experiments to be conducted at the risk of the lighting companies, and not at the expense of the ratepayers." After a long discussion the amendment was carried as an actual resolution by 22 votes to 21.

The electric light is, we understand, to displace the old oil arc burners in the theatre of the Hospital Institution, Albemarle-street, during the forthcoming Christmas and Friday evening lectures. The Swan lamp is now fastened along the gallery front, being strung between the brackets which are representing a species of "Swan with two necks." Other lamps are fixed in the centre roof, their light being directed, by means of a parabolic reflector, straight upon the stage, upon the audience. The arrangement and details have been carried out by Messrs. Woodhouse, Rawson, & Co., of Leicester-square. It has been found that 40 incandescent lamps thus disposed, light the theatre to the extent of 100 candle jets hitherto employed.

On Tuesday of last week a special meeting of the Town Council of Edinburgh was held for the purpose of considering a report by the Lord Provost and Magistrates recommending the council to apply for a provisional order under the Electric Lighting Act, 1882, in the course of some remarks introducing the business, the Lord Provost said that a good deal of influence has been brought to bear upon him, and he had had different companies had intimated their intention to apply to the Board of Trade for powers to supply the electric light for the streets and private houses. Intimations had been given that the authority of the council should be refused to the applicants, and the further consideration of the subject has been remitted to the Lord Provost's Committee; and the result of the deliberations of that body was that the council should be recommended to resolve on asking the Board of Trade for a provisional order enabling them to supply electricity within the Parliamentary boundary of the burgh, for public and private purposes, as provided for in the Electric Lighting Act. The Lord Provost moved in terms of the Committee's report. Bailie Stallan, and Bailie Hall seconded the motion. Councillor Cowan, in doing so, said he would remark that if they had any intention of granting companies in making their applications for the express result could be got for something like 8d., exclusive of the lighting of lamps and battery notices. In the Edinburgh Police Act, 1879, they had power to light the city by any means they thought proper, by gas or by any other method; and it had been thought by the Lord Provost's Committee that if they got a provisional order for adopting the electric light at any time they thought proper, they should have the whole lighting of the city at their command; and instead of the profits going to a speculative company, they would go into the pockets of the ratepayers. Other towns, such as Manchester, had made large sums out of lighting by gas, and he thought that such a considerable should be an inducement for their adopting the motion. The next speaker seemed somewhat surprised at the council making application for a provisional order if their Police Act gave them the power mentioned by Bailie Hall. While expressing approval of the motion, Dr. Rossell said he looked upon the Electric Lighting Act as one of the most mischievous Acts that had been passed for a long time. They were driven into applying for an order, not because the citizens were of opinion that the time had come for them to adopt electric lighting, but simply to save themselves from a monopoly. They were told that they were asked because they were not allowed to dig up their own streets and their own lighting! If there was any intention of a corporation that was thicker than another, it was surely the lighting of the town; but here they had a department of the Government put in control of their lighting. After some further remarks in the same strain, he expressed his belief that under their own Act they had the right to light the town with electricity or any other means that might seem good to them, and he only assented to the proposal on the distinct understanding that it was a bidding form. He urged that when the committee further considered the matter, they would not themselves into communication with the corporations of other large cities with a view to some joint scheme being struck out for resisting this encroachment on their rights and privileges in the management of their own affairs. Several other speakers indulged in some rather strong language in reference to the Electric Lighting Act, and the motion was agreed to, Councillor Cowan alone dissenting. The Lord Provost, by way of calming the growing excitement, remarked that they would have now to say that if the question could have been postponed for some time, because perhaps it was scarcely a practical question yet; it was still very much in the hands of scientific men, but they hands had now freed by the companies applying for licenses. One of the most important questions was a set of ordinances ready to put their claws into them, to seize the city and make profit out of it. He also remarked that electricity was still in its swaddling clothes, and that it only realised a light for their feast on the benefit of the experience gained elsewhere, and would be able to adopt it in the best possible way. After the foregoing was written the sub-committee entrusted with the matter met, and a draft application order was have done so, and instructions have been given to have it presented next Saturday (25th inst.).

Edinburgh has already had some experience with the electric light in the street lighting case, but the experiment was so unsatisfactory and so costly that the municipal authorities have not any predisposition in favour of the new light. For a considerable portion of the Princes-street half of Waverley Street and the North Bridge were in the hands of the "Brush" Electric Light Company, at the expense of the Corporation, and there were various explanations at the time as to the cause of the failure of the unsatisfactory results. There is no need to repeat them now. The lighting experiment was carried out on a somewhat large scale, there being a sort of desire to show the electric light and put them to supply gas on more liberal terms. Almost the only result to the Corporation as payments, is a larger gas bill this year, but combined with a better system of street lighting by the liberal use of "Argo" gas lamps in a number of the leading thoroughfares. Some years ago the Corporation of Edinburgh, on the recommendation of the Town Council, let down the gas supply undertaking of the city, but that desire is now scarcely often referred to, and it may be incidentally mentioned that the Waverley Station of the North British Railway Company has for many months been, and still is, lighted by electricity—apparently to the satisfaction of the company and the public.

The municipal authorities of Paisley and Hamilton, in both of which burghs the gas supply is in the hands

of the corporations, have issued statutory notices announcing the intention of those bodies to apply for provisional orders under the Electric Lighting Act to supply electricity for public and private purposes.

Letters have been sent by Mr. David Forsyth, the town-clerk of Elgin, to the town-clerks of a number of burghs throughout Scotland, urging the desirability of a joint representation being made to the Board of Trade in favour of delay being granted to them in the operation of the compulsory clauses of the Electric Lighting Act; and it seems that a meeting of representatives of certain corporations has been held in Edinburgh with the view of asking that they should be allowed to take the Act under permissive conditions, subject to the stipulation that a certain part of the community (including the corporations) should have in their adoption of the electric light, thereafter, to them the right of appeal to the Board of Trade. It is anticipated that another meeting of the Corporation representatives will be held prior to the 21st proximo (the last day for lodging formal notice of provisional order applications), for the purpose of considering what ulterior steps should be taken.

The town-clerk of Stranraer has been in correspondence with the town-clerk of Chesterfield in reference to the advantages of electric lighting, so far as experience has been obtained in that town, and the letter sent to him by Mr. Dods (town-clerk, Chesterfield) says: "The majority of the Corporation of Chesterfield are satisfied with the lighting of the town by electricity on the ground of efficiency and economy. We have twenty-two Brush arc lights and one hundred and fifty incandescent lamps at a cost, for the present year, of 3600 in place of 700 gas-lamps costing 900l. per annum. The streets are thoroughly well lighted. It is well to have accurate and positive statements as to cost, efficiency, &c., and I shall be borne out in general electric lighting practice or not. At present, such a statement is not to hand, as the Chesterfield electric lighting experiment has not been previously published.

At a meeting of the Police Commissioners of Stirling, held on Monday, the Lighting Committee recommended that the Commission should not apply for a licence or provisional order to supply electricity within the burgh under the Electric Lighting Act. In moving the adoption of the recommendation, Provost Yellowlees said that it would not be proper to ask the Board of Trade for powers which they never intended to use. Even supposing the new light turned out to be a success, he reminded them that no company had power to run in existence for a longer period than twenty-one years, and that at the end of that time they were required, if desired by the local authority, to give up all their appliances, &c. The committee were, besides, following the example of the Birmingham Town Council, who, after coming to a resolution, had made a very full investigation into the matter. The recommendation was agreed to.

The experimental lighting of Commercial-street, Dundee, by the Scottish Brush Electric Light Company, was commenced on the evening of Wednesday, the 15th inst. Five arc lamps of 2000-candle power each were used, and the current was generated by means of a Robey engine. The lamps, erected on poles about 25 ft. high, were placed about one hundred yards apart, so that they extended over a total distance of nearly a quarter of a mile. This is the first experiment in electrical street lighting in Dundee, and it is to be continued every evening for a month, commencing at about half-past four o'clock and continuing till eleven o'clock each evening.

In our last issue we gave some of the results of a special testing committee of the electric arc lights at the Paris Electrical Exhibition of last year. The same committee have also tested the electric candles exhibited there, and we are now able to give a summary of their report. The candles tested were those of Jablochkoff, Debrun, and Jamin. The Debrun machine is a dynamo, made for eight Jablochkoff candles, but having the same on the same axis. It was employed to feed seven Debrun candles; but for this only one of the two currents was utilised. The results do not therefore truly indicate the efficiency of this machine. The action was irregular, and the electrometres force varied from 40 to 60 volts. The Debrun candles burn downwards, and photometric tests gave about 21 carcels as the horizontal intensity of their light. Twenty Jablochkoff candles were fed by a Gramme machine, giving alternating currents and divided into four circuits, each bearing five candles. The measurements of work done were very variable. For the complete machine and twenty candles the

Total work expended in horse power (French) was 15.22
Single transmission 2.35
Effective motive work for twenty candles ... 12.87
" " " sixteen candles ... 11.36
Mechanical effect in open circuit 1.78
Lighting machine with one circuit and twenty candles machines with closed circuit; the work of transmission being deducted 3.06
Work expended by the single exciting machine 1.78

The photometric determinations were very numerous and concordant, and were made at a right angle, including 45 deg. on either side of the horizon. Twenty-five Jablochkoff candles were also fed by a De Meritens of five discs, having sixteen bobbins connected in tension, and feeding five circuits of five candles each. The Jamin machine fed 32, 48, and 60 Jamin candles. It is a self-exciting Gramme with four rings thus tinsel, and giving a quieter note. The candles were arranged in four distinct circuits. The photometric tests were only taken along a horizontal line. The annexed Table shows the detailed results obtained.

La Lumière Electrique states that the works of M. Lazare Weiller, of Angoulême, comprising foundries, rolling mills and wire-drawing establishment, have recently been completely lighted by electricity. The principal shops are lighted by 6 Gramme lamps, and the engine-room, offices and laboratory by Swan lamps; the current is supplied from two Gramme machines.

An electric lighthouse is going to be erected in New York Harbour. In accordance with the recommendation of the committee of experts charged with the selection of a site for a light tower three miles off will be built at Hallet's Point, Hell Gate, Congress having voted a sum of 75,000 dols. for the purpose. The height of the tower will be 250 ft., and the light will be about 20,000 candles.

At Buenos Ayres the inspector of public lighting who had been instructed by the municipality to prepare a report on the various trials of electric lighting that have been made in various parts of the town, has recommended the adoption of the Brush system.

It will be seen from this Table that the tests are in favour of the Jamin system.

Engineering, 14 July 1882

ELECTRIC LIGHTING IN THE CITY.

A REPORT to the Streets Committee of the Sewers Commissioners has recently been presented by Mr. William Haywood upon the prolonged experiment of street-electric lighting, which was commenced in April, 1881. This experiment was undertaken on the action of the Streets Committee, who were requested in March, 1880, to consider and report upon the adoption of an improved mode of lighting the City streets. This Committee considered it advisable that a trial should be given to the electric light, and in this view they were sustained by the Bridge House Estates Committee, who were also desirous of trying the experiment. These two bodies co-operating, decided upon lighting certain of the thoroughfares, including London, Southwark, and Blackfriars bridges, and it was arranged that while the Sewers Commissioners should undertake the management of the trial, the Bridge House Estates' Committee should pay the cost of lighting the bridges above mentioned. Acting upon this determination, tenders were applied for in the autumn of 1880, and were received from six different contractors. The area to be lighted was divided into three groups, and the tenders of three contractors were accepted. The main conditions of the experiment were, that it should extend over twelve months; that the lighting should continue each day from sunset to sunrise, and that no gas should be used, except as a substitute during the period of trial. The first district included a length of streets of 1648 yards, and an area of 98,887 square yards. It comprised Blackfriars Bridge; New Bridge-street; Ludgate-circus; Ludgate-hill; the north side of St. Paul's Churchyard; and Cheapside from its western end to King-street.

The second district, 1703 yards in street length and 87,264 square yards, comprised Southwark Bridge; Queen Victoria-street; Queen-street, Bowwark, to Victoria-street and Upper Thames-street; and Queen-street-place.

The third district, 1621 yards in length and 93,381 square yards in area, included London Bridge; Queen-street, between Queen Victoria-street and Cheapside; Cheapside, between King-street and the Poultry; King-street, Guildhall; and the Poultry; Mansion House-street; the open space in front of the Royal Exchange; King William-street, and Adelaide-place.

On August 1, 1880, the lighting of these three districts was allotted as follows: To the Anglo-American (Brush) Company, District No. 1, at a cost of 1410*l.*; to the Electric and Magnetic Company (Siebckhoff system), District No. 2, for 2920*l.*; to Messrs. Siemens Brothers, District No. 3, for 3720*l.* The second named company failed to carry out their contract, which was easily filled by Electric Light and Power Company, subject to much delay occurred before this company could begin the work that the twelve months of trial will not be completed before April next, so that the present report deals almost exclusively with Districts Nos. 1 and 3. Dividing the amount of each tender into per-manent works and cost of lighting, the three accepted tenders stood as follows:

	Per Weeks.	Per Lighting.	Total.
	£	£	£
District No. 1, Brush and No. 2, Electric Light and Power Company	720	690	1410
District No. 3, Siemens	1470	1450	2920
	1650	2270	3720
	3870	4290	8000

The quantity of light given for each district did not vary in anything like the proportion of the cost, as will be seen from the accompanying Table:

	Number of Lamps.	Nominal Candle Power per Lamp.	Total Nominal Power.
District No. 1	33	1000	33,000
,, No. 2	22	1000	22,000
,, No. 3	6 of large	2000	12,000
	126 small	300	37,800
	99		103,800

These lights replaced 166, 157, and 129 gas lamps respectively, each giving 14 candles, and represented a total illuminating power of 6328 candles, so that the electric light was about 16.3 times greater, while the total cost for gas during the year would have been 2026*l.*, as compared with the 1410*l.* for the electric light; rather more than twice the cost of gas for sixteen times the quantity of light. In making this comparison, however, it is only fair to point out the great difference in the prices charged by the various contractors; thus for the three districts, the relative cost of gas and electricity stood as follows:

	Cost of Gas.	Cost of Electric Light.
	£	£
District No. 1, Brush	690	690
,, 2, Lontin	390	1560
,, 3, Siemens	612	2772

The Brush lamps gave approximately 15 times as much light as the standard gas lamps; Lontin gave 14½ times, and Siemens 89 times as much light. The area thus illuminated was in all 1,090,410 square yards, or 1015 square yards on an average for each of the 99 lamps; the former lighted by gas averaged 929 square yards per lamp. It is not necessary to describe here the different modes by which each company carried out its work, for this we refer the reader to Engineering, vol. xxxi., page 335. But we may mention that the Brush Company and the Electric Light and Power Generator Company were very favourably situated, inasmuch as they were enabled to feed the lamps from their factories, while Messrs. Siemens were obliged to establish a special power station. Considering that each of the contending companies furnished nearly the same quantity of light, it is not easy to understand the wide difference that existed in the prices charged. The most interesting part of Mr. Haywood's report is that referring to the defects observed during the year. For the reason above stated, only Districts Nos. 1 and 3—Brush and Siemens—are reported on, the results in district No. 2 being incomplete. In District No. 1 there were 33 lamps in operation, each burning, on an average, 3030 hours, or 141,900 hours in all. There was a total of 620 failures reported, the aggregate resting, time of the light having equalled 3142 hours of a single lamp, or 2.21 per cent. of the entire year's lighting. In District No. 3 (Siemens) there were 81 lamps burning for a total of 140,800 hours during the year. In this district the total number of failures was 930, equal to an aggregate of 837 lamp-hours, or .57 per cent. of the total lighting.

On analysing these stoppages we shall find that considerable deductions must be made from each, before estimating the practical value of the systems for street lighting. The Brush lamps were started on the 25th of April, and on the 2nd of May it was found that the insulation of the main conductor was defective, and a new cable had to be substituted; this caused a delay of, seventeen days, on nine of which the system was not in operation, and a total loss of 2650 lamp-hours occurred. In the third district also, five days after starting, the [illegible] was damaged by [illegible] under London Bridge, and a total of 340 hours were lost in the illumination. It is clear, that the extinction from these causes have to be eliminated, as they were due to no defect in the systems, but to imperfect installation. These was, therefore, during the year, apart from these accidents, a loss of 612 hours in the Brush district, and of 372 in the Siemens, showing a slight advantage to the latter system, though for all practical purposes both were identical. It will be interesting to classify roughly the reported causes and extent of these interruptions:

	Brush. Hours.	Siemens. Hours.
Accidents to driving machinery through sudden	200.20	18.0
Defective	23	6.0
... ... or dirty lamps ...	6.10	214.0
Carelessness of attendants ...	110.0	144.0
Broken lamp-posts	163.0	6.0
Carbons burnt out	18.40	5.0
Short circuiting	9.0	7.20

The number of lamps affected by the delays as explained by the companies are as follows, exclusive of the accidents to conductors already referred to:

	Brush. Hours.	Siemens. Hours.
Defective machinery	24	122
,, carbons	24	121
Miscellaneous	24	7

The most striking feature in the above statement is the difference in the delays to the two systems caused by the carbons. In the Brush only 24 instances were recorded, involving a little more than six hours' delay on the year, which is practically nothing. On the other hand, the Siemens lamps were interfered with 104 times, and for 214 lamp-hours, or more than 30 days as much as the Brush. This is simply a question of detail, and proves what has always been claimed for the Brush system—the excellence of its carbons. It proves also that so far as carbons are concerned there is no difficulty in the solution of the problem of efficient street-lighting by electricity. On the whole, the total delays arising from breakdown of machinery, motors, or generators, only 128 hours' delay occurred in the Siemens system as compared with 209 in the Brush, and it is evident that while accidents are unavoidable, if proper precaution be taken in duplicating machinery, the delays arising from this cause can be reduced to such an extent as to be practically inappreciable. Still more striking is the difference in the trouble caused by carelessness, for while only the last 92 hours from this cause, Siemens lost no time at all. Of one of the systems, the broken lamp-posts, which resulted in 163 hours' delay in No. 1 district, it is clear that this cannot be charged to the unavoidable contingencies, although it must be borne in mind that the extinction of an electric lamp is a far more important matter than that of a gas lamp with regard to the streets.

It will be seen we think that the comparison made between the two systems after this extended trial is very satisfactory, because it proves that the chief proportion of the causes of extinction are easily to be avoided, excepting perhaps as regards the lamp mechanism which will probably be simplified as time goes on. It will be noticed that the delays from this cause were nearly equal in both systems, but while the majority in the Brush arose from defective mechanism, nearly all the Siemens are reported as "Lamps required cleaning."

It may be mentioned as an interesting fact that the total number of gas lamps in the city of London is 2326, and the number of lamps defective lights noticed during 1881 was 2505, a very large proportion, but which is neither so noticeable nor so important as a much smaller amount of defectiveness in the electric lights, on account, as above mentioned, of their greater power and more equable [illegible]

Concluding remarks was managed by Siemens [illegible] under London Bridge, and a total of 340 hours were lost in the illumination. It is clear, that the extinction from these causes have to be eliminated, as they were due to no defect in the systems, but to imperfect installation. There was, therefore, during the year, apart from these accidents, a loss of 612 hours in the Brush district, and of 372 in the Siemens, showing a slight advantage to the latter system, though for all practical purposes both were identical. It will be interesting to classify roughly the reported causes and extent of these interruptions:

	Brush. Hours.	Siemens. Hours.
Accidents to driving machinery through sudden	200.20	18.0
Defective	23	6.0
... ... or dirty lamps ...	6.10	214.0
Carelessness of attendants ...	110.0	144.0
Broken lamp-posts	163.0	6.0
Carbons burnt out	18.40	5.0
Short circuiting	9.0	7.20

The number of lamps affected by the delays as explained by the companies are as follows, exclusive of the accidents to conductors already referred to:

	Brush. Hours.	Siemens. Hours.
Defective machinery	24	122
,, carbons	24	121
Miscellaneous	24	7

The most striking feature in the above statement is the difference in the delays to the two systems caused by the carbons. In the Brush only 24 instances were recorded, involving a little more than six hours' delay on the year, which is practically nothing. On the other hand, the Siemens lamps were interfered with 104 times, and for 214 lamp-hours, or more than 30 days as much as the Brush. This is simply a question of detail, and proves what has always been claimed for the Brush system—the excellence of its carbons. It proves also that so far as carbons are concerned there is no difficulty in the solution of the problem of efficient street-lighting by electricity. On the whole, the total delays arising from breakdown of machinery, motors, or generators, only 128 hours' delay occurred in the Siemens system as compared with 209 in the Brush, and it is evident that while accidents are unavoidable, if proper precaution be taken in duplicating machinery, the delays arising from this cause can be reduced to such an extent as to be practically inappreciable. Still more striking is the difference in the trouble caused by carelessness, for while only the last 92 hours from this cause, Siemens lost no time at all. Of one of the systems, the broken lamp-posts, which resulted in 163 hours' delay in No. 1 district, it is clear that this cannot be charged to the unavoidable contingencies, although it must be borne in mind that the extinction of an electric lamp is a far more important matter than that of a gas lamp with regard to the streets.

It will be seen we think that the comparison made between the two systems after this extended trial is very satisfactory, because it proves that the chief proportion of the causes of extinction are easily to be avoided, excepting perhaps as regards the lamp mechanism which will probably be simplified as time goes on. It will be noticed that the delays from this cause were nearly equal in both systems, but while the majority in the Brush arose from defective mechanism, nearly all the Siemens are reported as "Lamps required cleaning."

It may be mentioned as an interesting fact that the total number of gas lamps in the city of London is 2326, and the number of faulty defective lights noticed during 1881 was 2505, a very large proportion, but which is neither so noticeable nor so important as a much smaller amount of defectiveness in the electric lights, on account, as above mentioned, of their greater power and more equable [illegible]

In a report of the Streets Committee to the Commissioners of Sewers, some detailed information is [illegible] on a proposed project to extend the experiment of electric lighting in the streets to four districts, one of which is the District No. 3 of last year. Eight tenders for this work were submitted, with the following general result:

	Tenders ranged from	Cost of Gas.
District No. 1	2190 to 6750	510
,, ,, 2	2250 to 6700	360
,, ,, 3	2470 to 5000	241
,, ,, 4	2000 to 4350	312

Some of the contractors coupled with their tender the request to be allowed to light private premises within the districts, and in one case the company offered to make the charge for lighting (not including installation) 20 per cent. more than the cost of the gas saved. None of the proposals made were of such a character as to justify the Streets Committee in recommending an extension of the experiment, particularly as by the Bill now before Parliament, and the amendments suggested by the Board of Trade, it is proposed to give power to local authorities to supply electricity not only for public but for private use; until this important question has been settled, the Committee deem it unwise to incur further expense in the matter.

It has been decided, however, to continue the lighting of District No. 3 for another year, the Anglo-American (Brush) Company having undertaken the work for 800*l.* An offer made to Messrs. Siemens to continue the lighting of District No. 3 for twelve months further, for which they asked 2400*l.*) was considered too high, and the Commissioners have returned to gas in this district. We should mention in conclusion that Mr. Haywood speaks very favourably of the Holborn Viaduct lighting on the Holborn Viaduct, and promises a special report on this installation, as well as on the District No. 3, which is being lighted with Weston lamps by the Electric Light and Power Generator Company.

Engineering, July 6, 1883.

On Friday evening last, by permission of the Fine Arts Committee of Works, the Swan United Electric Light Company gave a reception at the Royal Courts of Justice to show the efficiency and success of their installation there, which consists of 628 incandescence lamps and six Crompton arc lamps of the kind illustrated in ENGINEERING, vol. xxxv., page 246. These are from 22 to 24 Swan lamps arranged in each of the 20 courts, and the remainder are distributed through the cloisters, staircases, refuge rooms, &c. Each court, and its anteroom is on a separate circuit, and the whole of the circuits on each side of the building converge to a switch board, where they can be turned on and off as desired. The generating machinery is temporarily situated in an iron building on the west side of the courts. It is not decided whether the machinery will remain in this position or whether it will be transferred to the great outer the Queen Hall. If kept at or near its present position it is intended to sink it below the surface of the ground and arch it over. The plant consists of a semi-portable compound engine by Messrs. Marshall and Co., and eight Crompton-Burgin dynamos. Six of those latter are compound wound and deliver their current into the main leads that connected the engine-room to the switch boards in the vaults of the main building. The guarantees said and feed the whole of the lamps at the same time, Power is also supplemented by 20 two horse-power Faure-Sellon-Volckmar accumulators, which are charged during the day-time, when fully charged, are sufficient to light all the courts for eight hours. The result of this division of the machinery has been that there has not been the slightest interruption of the light due to any failure in the machinery since the installation was put in operation at the opening ceremony on December 10. It is estimated that the cost of maintenance will not exceed 25*l.* per week, whereas the cost of lighting by gas would have been from 40*l.* to 50*l.* We believe that the Judges and the Bar have uniformly expressed themselves extremely satisfied with the result of the lighting.

The Marquis of Salisbury has recently applied the electric light to the reception rooms in his house in Arlington-street. The marble staircase is lighted by fifty-one Swan lamps arranged on a dark bronze chandelier, and there is also a corridor in which the lamps are hung from gilt crowns under a vaulted roof. The first reception room there is a magnificent chandelier in ebnd gold, carrying 100 lights, and in the second, or Doncaster room, there is a similar fitting with 78 lamps. Formerly wax candles were used, and the sockets in which they were held have been removed and replaced by incandescence lamp-holders, the greatest care being taken to hide all the connections. As the branches were not hollow it was necessary to carry the conductors outside them, but they have been so skilfully fixed to follow the same lines of curvature, and have been overgrown with silk of the same colour as the ground, bright or dead gold or bronze, so that very little searching is needed to detect their presence. The globes of the lamps are slightly frosted, but not to any great degree, and they are entirely without shades of any kind, and appear all the better for the outside. The brightness of the illumination increases gradually from the ante room to that the visitor is more ornate apartments, which are the most vividly lighted. The current is generated by a compound wound Siemens' dynamo, situated in an outbuilding and driven by an Otto gas engine of 10 nominal horse-power, which is being driven to nearly 25 from that source. Very careful arrangements have been made to secure steady motion; there are two exceedingly heavy flywheels on the engine, a second on the crankshaft, and a third of unusual size on the fly-wheel, and by these means very good results have been attained. The installation, which is probably the largest and certainly the most successful of any hitherto erected in a private house, has been entirely designed and carried out by Mr. Shillito, the marquis's engineer, and reflects great credit upon his skill and artistic feeling. As many of our readers are aware, this is not Mr. Shillito's first essay in electric lighting, for he had under his charge at Hatfield Park both Brush, Gramme and Siemens machines with their respective lamps. The power is there derived from a waterwheel two miles from the house, so that the current is made to do a good deal of work on the estate. As long as two years ago it was employed in quarrying, pumping, and sawing, and now it is in addition to use it in dredging the ornamental waters in driving the rasping machine. When these latter objects are accomplished we shall publish a description of the apparatus employed by Mr. Shillito, who appears to be one of the very few people who have succeeded in making a practical use of the electrical transmission of power.

ELECTRIC LIGHTING.

Lauriston House, Dromley, the residence of Mr. Swan, is lighted throughout with electricity, and forms one of the most interesting private installations yet made. It is remarkable for its completeness, every room and closet being lighted by the current; even the coal cellars, and the gate lamps. The lights are all commanded by small switches suitably placed so that a person entering a room, say a bed-room or closet, can light it up before going and darken it on leaving again. The switches for this purpose are placed near the doors either outside or just within. Again, if a light is wanted at the bedside or the writing-desk it can be had in a moment by touching the proper switch. One of the beds has a reading lamp just over the pillows for an invalid who desires to read, and the switch is ready to his hand. The gate lamps are controlled by switches in the engine-house. The drawing-room is lighted by three very elegant chandeliers made by Formley. They are of brass work, and each holds six lamps shaded with blue glass cups. The lamps are controlled by switches, one for each chandelier, fitted into the wall. Besides this there are six wall bracket lamps with crystal reflectors behind. Each of these and in the dining-room, fashed throughout the whole house, the lamps are fitted up with great taste, and at the same time economy. In the dining-room the chandelier and brackets are by Elkington, the globes being of the new crinkled glass, which has a very pretty effect, like rough ice. The illuminants in all cases, except where naked lights are used in the cellars, are units shaded from the rays by the ground glass or crinkled globes. In the drawing-room this effect is produced by having the bulbs themselves of ground glass. The dining-room table is further lighted by two brass standard lamps which are placed on it when required and connected by wires through the tablecloth, table, and floor. These connexions are made by leaklins running through the tablecloth into the table. Moreover, a large Japanese calabash filled with roses and used as a centrepiece has several lamps hid amongst the flowers; and these are lighted up in the same way, producing a very pretty effect, the lamps resembling yellow roses. An artificial lemon-tree has its fruit lighted internally in the same way. By means of a small Thompson motor Mr. Swan also employs the current from a lamp at will to drive a sewing machine or coffee mill. Light for candles, or fire for the cigar is also obtained from the lamp's current by means of a small device invented by Mr. J. E. H. Gordon. This consists of an ebonite handle, with a disc gaunt, like a finger buff, and having in front of the disc, where the blade should be, a spiral of bare platinum wire terminating in a plug of fire-clay. When the current from a lamp is sent through this wire by means of insulated wires running through the haft, the platinum gets heated up and a light can be obtained from it. There are between sixty and seventy lights on Mr. Swan's premises, including two in the engine house. They are supplied by two Otto gas engines, each of 4 horse-power nominal, but capable of developing 6 horse-power. Each drives a Siemens continuous current dynamo of the smallest size, and thirty Peare-Selion-Volckmar accumulators are charged for an hour before the lighting begins. These accumulators serve to supply extra lamps when wanted, the two dynamos only supplying thirty lamps when running on their alone. The accumulators can be kept partially charged by a by-circuit while the machines are running. They maintain the extra lamps required on special occasions, and also yield occasional lights during day. The engines consume 76 cubic feet of gas per hour, and this expended in gas lighting would give thirty gas jets of 16 candle-power; but the electric lights are rather over 16 candles (they are 20-candle lamps) and the light is far more pure, agreeable, and healthy.

ELECTRIC LIGHTING NOTES.

During the last trip to America and back of the City of Rome, the electric light machinery supplying the lamps in the boiler and engine-room was run continuously during the whole voyage with a single stoppage of twenty minutes for inspection in New York Harbour. This is probably the longest trial of the kind, and speaks well for the endurance of the Siemens apparatus on board, and for the care of the engineers to whom it is intrusted.

The Maxim-Weston Electric Light Company have decided to abandon their City circuit pending the time when the Commissioners will be in a position to parcel out the City in large sections. The cause of this determination is stated to be the great expense of maintaining a central station to supply so few lights. These are of the firms who originally undertook to light the City of London have acknowledged that the contract price was quite inadequate to repay them their actual disbursements. The third contractors, the Brush Company, are much more favourably situated than the other two, as their lights are driven from their own works by a single machine, hence the cost for rent and attendance is extremely small. At the same time it is not to be supposed that the charge they make to the City, 600l. a year, indemnifies them.

The Criterion Theatre, Piccadilly, is to be lighted throughout with about 600 Edison incandescent lamps, the generating plant will comprise two Lumington and Sims' horizontal high speed engines, having 13 in. cylinder by 13 in. stroke, running at 275 revolutions per minute, and driving on to countershafting from which will be run four Edison-Hopkinson dynamos, each capable of sustaining 150 sixteen-candle lamps. Each engine will be capable of indicating eighty-four horse-power at 70 lb. pressure, and either engine will thus be able to take the whole load in the event of accident or repairs to the other. The wiring will be arranged on the three-wire system, under independent control by means of a specially designed regulator capable of lowering or raising the intensity of the lamps from normal candle power to nil. The contract for the work, which will be carried out by the Edison Electric

Engineering, Nov. 16, 1882.

ELECTRIC LIGHTING NOTES.

A very complete system of incandescence lighting has just been carried out on the Tasmania, the first of the magnificent steamers constructed for the Messrs. Robert Napier and Sons, Glasgow, intended for the passage and mail service between Adelaide and the Continent of Europe. The whole of the electric lighting plant required in connection with the specification and under the immediate superintendence of Professor A. Jamieson, C.E., F.R.S.E., of the Glasgow and West of Scotland Technical College, and the contract has been executed by Mr. Richard Miller, electric lighting engineer, Glasgow. There are about 1200 Swan lamps in the installation, each of 20-candle power; and the current is obtained from one or other of two Siemens dynamos, compound wound dynamos, which are capable of developing a normal, an electromotive force of 60 volts. These machines are worked by independent and separate engines. The larger of the two dynamos is capable of running 200 lights, and the other, which is kept in reserve for working the night circuit, or brought into use when the large machine is being overhauled, is powerful enough to work about 50 lamps. In laying down the leading wires the method adopted has been to carry the ship as an "earth" return, and in consequence extra precautions were taken, not only in obtaining the very best insulated electric light leading wire in the market, but also in securing the slip throughout against possible danger. The whole of Company's best insulated cables and Gutta Percha no instance are there more than 50 lamps under the control of any main switch, in order that minimum the number of lamps switched on or off; and in all cases they are placed under the control of one or other of the petty officers of the ship, or those of the steward's staff; each lamp is provided with two leads of flexible wire, and may be turned out without any regard to the other lamps in the circuit. The main cables is provided with all fuses in the usual way. These are gold-plated, and are suspended one above the main table, electric lamps are disposed in pairs on opposite sides of the oil lamps, and are fitted with Swan's latest form of lamp-holder. Wherever it has been found possible in the state rooms, the Edison switches &c., the lamps are placed in neat translucent lanterns (the shoe being flat and formed of ground glass), which are so disposed as to light two rooms. In the engine room and stokehole a special form of lantern, specially designed, consisting of a hemispherical glass case fixed to the bulkhead by means of screws, in the centre of convenient ideas for showing the working parts of the engines, the gauge glasses of the boilers &c. The engines for driving the dynamos, which have been fitted with Pickering's governor, were made by the firm of Ashworth, while the gearing requisite for distributing the necessary speed was devised by Mr. A. C. Kirk of Messrs. Napier and Sons, and made by Messrs. C. and A. Harvey, the well-known machine tool manufacturers. The dynamos are carefully insulated for the ship and engines by means of an insulated coupling and bedplate. Steam is supplied to the engines from the main boilers at a pressure of 140 lb. per square inch, which is the highest pressure yet employed on any large steamer. The engines used for the large dynamo, is capable of developing about 75 horse-power, and the other is equal to from 7 to 8 horse-power.

THE EDISON SYSTEM OF ELECTRIC ILLUMINATION.

We now come to refer to the very ingenious apparatus employed under the Edison system* for measuring and recording the quantity of electricity that has been transmitted from the central station into the electric mains for utilization in the various circuits, as well as that for indicating the quantity of current that has been used by any one consumer, and upon the indication of which the company's account against him is made out. The principle of action of both the instruments employed, depends upon the fact that the weight of metal deposited per unit of time in an electro-plating bath by electrolysis is proportioned to the quantity of electricity passing through it in the same period, or, in other words, to the strength of the current, and as the amount of this electro-deposition is equal at all points of a circuit, it follows that by placing an electrolytic cell in any part of a circuit, the amount of electricity transmitted by the cell in a given time can be determined by observing the quantity of metal deposited within the same period.

The apparatus employed in the Edison system in connexion with the service of a house is illustrated in Figs. 1 and 2 (see next page).

The house meter consists generally of two electrolytic cells so connected as to form together a shunt to the lighting current, and also so arranged that one cell is capable of transmitting a greater quantity of electricity than the other, the proportion between them, however, remaining the same. The two cells are fitted into a small cast-iron cabinet, as shown in Fig. 1, and below them is a simple automatic arrangement, to be after described, for preventing the temperature of the cells from falling below a certain degree.

In the earlier form of meters devised by Mr. Edison the cells employed were a solution of copper sulphate, the electrodes being of pure copper, but in the more recent instruments the copper solution has been replaced by a solution of zinc sulphate and electrodes of zinc, by which arrangement most objectionable currents are reduced to a minimum and many other results are insured.

Referring now to Fig. 2, V and V' are the two electrolytic cells, each of which is filled with a solution of zinc sulphate, in which is immersed a pair of amalgamated zinc plates. The two cells are precisely alike, save in the fact that the one cell is short-circuited by a shunt having one-fourth the resistance of the coil by which the other is short-circuited, the quantity of electricity passing through the former is consequently four times that which is transmitted by the other, and therefore, within a given period, the quantity of metallic zinc deposited on the receiving plate of the one cell is four times that which is deposited on that of the other. The short-circuiting shunts are shown at S, and consist of a corrugated band of German silver, of which the twelve corrugations towards the left of the figure constitute the shunt of the cell V, while the remaining four corrugations belong to the right-hand cell V'. L is an ordinary Edison incandescence lamp, at the point A, and this is effected by the bending downwards of the compound expansion bar A B, which is so constructed and adjusted as automatically to throw the lamp into circuit whenever the temperature within the instrument falls below a certain point. The radiant heat from the lamp then raises the temperature of the air within the apparatus until by the upward curling of the compound bar, the lamp is again put out of circuit; r and r' are wire, which are included in the branch circuit of the electrolytic cells, their object being to keep the resistance of the apparatus uniform under variations of temperature, for, as the resistance of the zinc solution within the cells is diminished by a rise of temperature, the quantity of electricity transmitted by it would be greater as the temperature was increased unless this increase were compensated or neutralized. To effect this a coil of copper wire is inserted in the circuit of each cell, and as the electrical resistance of copper increases with a rise of temperature, while that of the zinc solution diminishes, it is only necessary to make the length of the copper wire such that its resistance rises under an increase of temperature as much as that of its corresponding cell diminishes, in order to compensate the apparatus for variations of temperature. The method by which the various parts of the apparatus are coupled up will be understood by

* See Engineering, page 407 ante,

referring to the diagram Fig. 2, which also illustrates the position of a lamp circuit with respect to the meter.

The object of having two cells instead of one is to enable the supplying company to keep a check upon the inspectors, and also to guard against fraud on the part of dishonest consumers, for while the left-hand division of the meter is accessible to the ordinary inspectors, and in some cases to the consumers themselves, the right-hand portion is under the sole control of the company through their superior inspectors, and the readings of the two cells should always be in the same proportion to one another. Again, the object of causing the one cell to deposit slower than the other is that while the ordinary inspectors go their rounds once a month, the upper inspectors visit the meters once a quarter; the one cell is therefore depositing for four weeks between two inspections, while the other is in action for thirteen weeks before its plates are weighed again; and, by causing the three months' cell to deposit slower than the one month cell, the amount deposited in each between any two inspections is more nearly equalized.

The zinc plates are shown in detail in Fig. 4; they are 3 in. long, 1 in. wide and ¼ in. thick, fixed at a distance of .24 of an inch by fastening two little ebonite blocks of that thickness between the plates, the one at the top and the other at the bottom (as shown in the figure), and then holding the whole together by an ebonite screw passing through the middle of the plates before being put together, however, a coating of chemically pure zinc is deposited by electrolysis upon the surface of each plate so as to reduce local action to a minimum, this operation being performed in a chemically pure solution of zinc sulphate, and the plates are afterwards amalgamated with pure mercury.

When the apparatus is set into action also by dissolved off the one plate of each pair and deposited upon the other, and the quantity of zinc transferred from the one plate to the other is proportional to the total quantity of electricity which has passed through the cell and is independent of the time, if it be only necessary periodically to weigh the plates in order to ascertain the quantity of electricity which has been utilized, and it is immaterial whether a current of one weber flows for ten hours, or one of two webers for five hours, or of five webers for two hours, or of ten webers for one hour, the transfer and deposition of metal will in all cases be the same.

The consumer is charged so much per weber of current passed through the meter per hour. The inspectors go round once a month collecting the cells and substituting fresh ones in their place; each cell on being removed from the meter is placed in a separate compartment of a basket, its number being carefully noted. The cells as removed are taken to the central station, where the pairs of plates are separated and accurately weighed in a delicate balance, the results being entered in the meter-book, of which a specimen page is given below. The weber current that has passed through a "25 light" meter since the last observation is calculated by the following formula:

$$\text{Webers} = \frac{W}{1{,}232}$$

in which V represents the weber current that has passed per hour, and W the increase in weight of the receiving plate since the last observation, the figure 1,232 being the number of milligrammes of zinc deposited per weber per hour. It must be supposed that a set of zinc plates before being put into action weigh as follows: that in the monthly cell, 92,800 milligrammes, and that in the accompanying quarterly cell, 92,000 milligrammes, and that after having been in use for a month in an installation of twenty lights burning about four hours a day they weigh as follows:

	Milligrammes.
Monthly cell	95,307
Quarterly cell	95,255·3

Subtracting these weights from the first we get a difference in the monthly cell of 2517 milligrammes, and in the quarterly cell of 629·2 milligrammes, and if all has been working well the increase in the weight of the quarterly zinc should be about one-fourth that of the monthly plate. Applying the above formula to these figures we get the figure 1,833 as the number of webers passed through the apparatus per hour, and it is upon this figure that the consumer is charged. The following is a specimen page of a meter book, showing the general form of the entries and the principle upon which they are made:

Meter Number.		Name of Consumer.		Address of Consumer.	
Plates put in.	Weight of Plates.		Plates taken out.	Weight of Plates.		Gain.		Webers Consumed.
	Monthly.	Quarterly.		Monthly.	Quarterly.	Monthly.	Quarterly.	
January 20 ...	90,500	90,400	Feb. 20 ...	91,400	...	1100	...	833·3
February 17 ...								
March 17 ...								
April 14 ...								
May 12 ...								
June 9 ...								

The Edison meters of the form illustrated in Fig. 1 are at present constructed in two sizes, the one for currents of twenty-five lights, and the other for fifty lights is a circuit. In the former apparatus the monthly cell deposits per webers 1.356 milligrams per hour, the deposit in the quarterly cell being about one-fourth of that amount. In the fifty-light meter the rate of deposit is 1.277 instead of 1.356. The zinc solution is made as follows: 90 parts by weight of pure zinc sulphate is dissolved in 100 parts by weight of distilled water, and if the solution has been properly made, a hydrometer should show a specific gravity of 1.33 at a temperature of 15 deg. Cent. We may mention here that Mr. Francis Jehl, who has been associated with Mr. Edison throughout the development of his very interesting meters, has recently been contributing a very careful series of experiments upon the specific resistance of various solutions of zinc salts, and on another page of our present issue we give the results of some of Mr. Jehl's experiments.

The most interesting and elaborate apparatus of this kind designed by Mr. Edison is the automatic motor or electric counter represented in Fig. 5, and which is rather suited to the laboratory of the central station, where it can be in proper and intelligent hands, than to house or factory installations, where it might soon be put out of order. The apparatus consists of two electrolytic cells, each containing a solution of copper sulphate, and in each of them is immersed a hollow cylinder of copper. Within this cylinder is suspended from the end of the beam of a small-size balance, another copper cylinder; the two cylinders in each cell constitute the electrodes of an electro-depositing bath, and according as to whether the current traversing the cell is in one direction or the other, so will the metallic copper be transferred from the fixed cylinder to the suspended cylinder, and *vice versâ*, and the connexions are so made that while the apparatus is depositing copper on the inner cylinder of the one cell, metal is being dissolved from the inner cylinder of the other cell; thus while the one is, during the passage of the current, becoming heavier, the other is losing weight. It is clear from this construction that a time must occur when the one will overbalance the other, and the beam will then depress its deflector; in this state the current is automatically reversed, and, traversing the cells in the opposite direction, the process is

THE EDISON SYSTEM OF ELECTRIC ILLUMINATION.

electromagnet being diverted from the heavier suspended cylinder, while the other is receiving a deposition in the other cell until it overbalances the first, causing the beam to be depressed, and again reversing the current sets the instrument to its original position; the process is thus repeated and repeated again, as long as the current passes. Connected to the beam by suitable mechanism of an ordinary counter, by which the number of oscillations of the beam is recorded, and as each oscillation represents a deposition of copper to a certain weight, and that weight is a measure of the quantity of electricity flowing through the instrument, the current is measured by a process almost identical mechanically with the method by which the quantity of gas being utilized in an establishment is recorded. The above is a description of the general principle upon which the automatic meter works. It will be seen, however, on reference to the illustration, that there are certain electro-magnetic attachments and switches. The principal object of these accessories is to insure the beam tumbling over to one side or the other the moment that the quantity of metal to which the instrument is adjusted has been transferred from the one electrode to the other, for as the electro-light action is very gradual, it would be quite possible for the beam to stop at its central position when equilibrium has been established between the two balanced electrodes, and contact might be broken on one side without being made on the other, and the action of the instrument would cease, although the current might be utilized throughout the installation. By the electro-magnetic attachment, however, the apparatus can be so adjusted that the very slightest motion of the beam to one side or the other of a certain fixed point makes an electrical contact, thereby throwing one or other of the electro-magnets into circuit, and by the attraction of an armature causing the beam to fall over. There are other interesting details in Mr. Edison's meters, but they are hardly important to the subject of these articles, whose object is rather to describe a system of electric illumination than the details of every piece of apparatus employed in connexion with it.

Connected with the system, however, there are several interesting accessory instruments, one of the most original and curious of them being the apparatus illustrated in Fig. 6, which is a very ingenious and interesting form of resistance "box" devised by Mr. Edison, and which has on the top the usual set of connecting plugs and contact pieces; instead, however, of coils of wire forming the resistance, the lower part of the upper table is pierced with lamp sockets, the two terminals of each being connected to a corresponding pair of contiguous contact pieces. Into these sockets are screwed as many lamps, and the carbon filaments of which constitute the resistance can be thrown into or out of circuit by removing or inserting the connecting pegs in the usual way.

In the instrument shown in the figure there are ten lamps, and these can be thrown into a circuit in exactly the same way as are the coils of a resistance box. It is not claimed for this instrument that it is an accurate measure of resistance, but it is very useful and convenient for increasing or diminishing the resistance of a circuit by the equivalent of so many lamps inserted either in the circuit or as a shunt, and it may also be used for testing lamps and ascertaining how many may be used in any particular circuit.

With this apparatus we shall bring this series of articles to a close. We shall, however, notice any interesting improvements or additions which may from time to time be made to this important and rising system of electric illumination introduced by Mr. Edison.

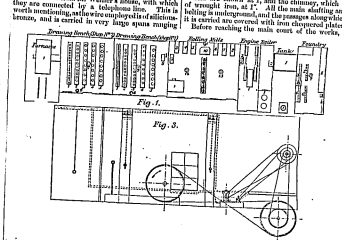
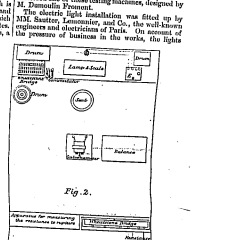
AN ELECTRIC LIGHT INSTALLATION.

We have on several occasions referred to the phosphor, and silicium-bronze telegraph and telephone wires manufactured by M. Lazare Weiller, of Angoulême, and have published the very interesting results obtained by him with them. The demand for wire of this kind has become so extensive that M. Weiller has recently constructed entirely new works adapted for a very considerable output, and in them he has mustered a large number of special tools and experimental apparatus. The Fresnays Works are situated in one of the suburbs of Angoulême and at a distance of some miles from M. Weiller's house, with which they are connected by a telephonic line. This is worth mentioning, as the wire employed is of silicium-bronze, and is carried in very large spans ranging from 600 ft. to 1000 ft. We need not stop here to consider the various processes of manufacture of the phosphor and silicium-bronze, nor their conversion into wire. The various operations involve very skilled labour, and special processes, some of which are kept secret. On the present occasion we have especially to do with the electric lighting installation, and the instruments for electrical measurement, and we may appropriately give in this connection some description of the arrangement of the works. The establishment of M. Weiller consists of two main buildings, which are shown in the diagram plan, Fig. 1. On the left of this diagram will be seen a rectangular building with two wings, 295 ft. 7 long and 52 ft. 6 in. wide, divided into five parts, which are respectively: 1, the engine room; 2, the rolling mills; 3, 3, the two wire-drawing shops; 4, the forges; 5, the annealing furnaces. The second portion arranged transverse to, and at the end of, the first one, is separated from it by a space of 33 ft. It is 39 ft. 9 in. wide and 52 ft. 6 in. long, and forms the foundry. In front of these two buildings, which are of stone, and well lighted and ventilated, is a large court-yard, around which are placed accessory buildings. One of these comprises the chemical laboratory, in which are made the analyses of copper and bronze. In an annexe to the building are prepared the alloys used for the deoxidation of the bronze (phosphor or silicium), and adjoining it are the drawing and general offices. Finally, opposite the foundry, and about 200 ft. from it, is a small wooden building, containing the apparatus used to measure the electrical and mechanical resistances of the wire. The former forms a separate shop, in which the ingots and other castings of phosphor-bronze are produced. It furnishes besides about two tons of alloy per day, which are cast in bars and passed on to the wire-drawing shops for making conductors. It contains 12 furnaces in two groups of six (2, 4) separated by a chimney. In front is a casting pit (6, 6) containing the ingot moulds. The drying ovens are shown at 3; 9 is a shears, and at 7 is an electric lamp, of which we shall speak presently. The rolling mills and the drawing benches occupy the central part of the large building. In the former shop, as shown in the plan, are placed the annealing ovens, 1; the drums, 2 to 8; the counter shafting and the rolling mills, 10, 11; while 12, 13 are two drawing shops contain the benches, 1—5; the electric lamps, 7; and a pointing machine, 8. In this part of the factory are carried out all special work for the production of telegraphic and telephonic wires. The rolling mills and drawing shop have two wings, the first of which contains annealing ovens, supplied by a small reverberatory; the second forms an engine room, the engine being 200 horse-power compound, made by MM. Weyher and Richemond, of Pantin. The boilers are shown at 1, and the chimney, which is 90 ft. of wrought iron, at 1'. All the main shafting and belting is underground, and the passages along which it is carried are covered with iron chequered plates.

Before reaching the main court of the works, a



garden has to be traversed, which forms part of the works. Between the garden and the courts is a small river called the Jequienne, on which are situated the washing establishments of the ore before the pickling and subsequent annealing of the wire is performed. These latter operations have a special importance, and require quite a series of separate buildings. A little above, a covered bridge has been formed, leading off a part of the water from the river across the court into the factory, where it passes into a filter and then into a well from which it is taken into the boiler. Before this, however, it is raised by a Gwynne pump into a large iron tank, containing about 1800 gallons. This tank is carried at a height above the ground of 32 ft. 9 in. on twelve cast-iron columns. From this it goes to the boiler, while the condensing water passes back to the river, at a point below the works. The electric installation comprises a laboratory for tests, and a lighting plant. The former has been established under the direction of an eminent electrician, M. Ledoux, professor of electricity at the school of submarine defence works, at Boyardville. The general arrangement is indicated on the sketch plan, Fig. 2. In the middle of the room is fixed a heavy stone pedestal, surmounted by a pyramid of wood, which carries a Thomson mirror galvanometer. To this are led the wires from the various measuring instruments in the room: those instruments are placed on two tables along the whole width of the laboratory, in front of, and behind the galvanometer. The wires are insulated, and lie in grooves made in the floor, and in the side of the pyramid carrying the galvanometer. To each apparatus belongs a double direction galvanometer, by which the current can be passed in any desired circuit. Above are placed cylinders with helicoidal grooves, round which are wound the wires subjected to trial. The circumference of the cylinders being known, the number of convolutions of the wire, give the length by observation. The wire is rolled upon a second drum, whence it is led to the grooved cylinders. In this way tests of considerable length of wire can be made. Opposite the galvanometer, and 23.62 in. above one of the tables, is fixed the graduated scale with its lamps. The other apparatus include Wheatstone bridges,



resistance coils, &c. The measures chiefly made in this laboratory are those relating to the conductibility of the various wires of copper, phosphor and silicious bronze, steel, iron, &c. In the same room are also effected the tests relating to the mechanical resistances of the wires, their extension under a given load, the number and extent of bendings they will sustain, and the general tests of their quality as required by the specifications of the Government railway companies and other purchasers. We have already on a previous occasion described one of these testing machines, designed by M. Deneulin Froment.

The electric light installation was fitted up by MM. Sautter, Lemonnier, and Co., the well-known engineers and electricians of Paris. On account of the pressure of business in the works, the lights have been in operation nearly all night for some months past, and have given great satisfaction, both on account of the luminous value produced, and the economy obtained. Two Gramme generators are employed; one of these, a Gramme B machine with diet electro-magnets, feeds five Gramme lamps; the other, a small Gramme machine, supplies the current to 15 Swan incandescence lamps. The power required to drive the dynamos is taken off the main countershaft which is in the same room with the regulators as shown in the general plan. The main shaft is driven at 200 revolutions, and on it are two pulleys, one 27.79 in. in diameter for the large generator, and the other 23.61 in. for the small one. These are driven as shown in Fig. 3, and give a speed, the first, of 1000 revolutions with a pulley 7.87 in. in diameter, and the second of 2000 revolutions with one of 5.94 in. In reforming once more to the well-known reputs of MM. Mascart, Joubert, &c., we find that with a speed of 1406 revolutions an F. C. Gramme machine absorbs about 8 horse-power, and gives out 44 the lamp the following intensities:

112	carcels,	horizontally
166	"	maximum
97	"	mean spherical.

At the Fresnays Works the power absorbed in somewhat less (6 to 6 horse-power), and the luminous values would, therefore, be somewhat inferior. The Swan lamps have each a luminous intensity of about 1 carcel (8.6 candles), and the motor supplying them uses 1½ horse-power. The Gramme lamps take a current of 16 amperes; the Swan lamps one of 2 amperes. The five Gramme lights are distributed as follows: One in the foundry, two in the rolling mill shop, and two in the wire-drawing shop. The engine-room is lighted by four Swan lamps, and these also serve as signal lights to check the proper working of the generator. The others are divided between the laboratory and testing room and the offices. As the generators are driven off the main engine, and as the load on this engine is very variable, it has been found necessary, especially for the small generator, to interpose a resistance commutator, adjusted by hand, so that a constant luminous intensity can be obtained. The appliances described, produce a total luminous value of 560 carcels from the five arc lamps, and 15 carcels from the Swan lights, in all 575 carcels, or nearly

ELECTRIC LIGHTING NOTES.

The Journals des Printemps in Paris, which was destroyed by fire about two years ago, has been rebuilt on a magnificent scale, and will shortly be opened. It will be lighted by Jablochkoff candles.

The establishment of Messrs. Keys Brothers and Sims, of Donegal, have been lighted by four Fillan arc lamps, and candles, and the remainder inside the building. The installation has given great satisfaction; it was carried out by Messrs. Woodhouse and Rawson, of 11, Queen Victoria-street, London.

Messrs. Siemens Brothers and Co., 10, Great George-street, Westminster, London, agents for the Siemens United Electric Light Company, are exhibiting at the Royal Aquarium Exhibition, about 200 Swan, incandescent lamps of various sizes from two to fifty candle power. These light their court, a portion of which is divided off and furnished as a complete modern dwelling-room. The current for maintaining these lights is derived from a Siemens' 200-light alternating-current dynamo-machine and feeder, worked from the main shafting in the engine-room. The same firm are also exhibiting a Siemens' 50-light dynamo-machine, maintaining the lights in the drawing-room, the first current being supplied by a Siemens' direct current dynamo-machine driven by a 3½ horse-power Otto gas engine, which is worked by means of Bowman's gas manufactured in the Exhibition by the Bowman's Economic Gas Company. The whole of the furniture and fittings are carried out by the exhibitors, being either manufactured by them or expressly for them. Finally, Messrs. Elmenhorst exhibit from one of their outside towers a 4000-candle power arc light, in a fireproof lantern, as used for lighthouse purposes, and for throwing a parallel beam to the horizon. The current for this is obtained from a Siemens machine, and the lamp used is of the Serrin type.

The Electric Exhibition at the Crystal Palace is still very disappointing. Although it has now been open for two months, many of the promised exhibitors have not as yet put in an appearance, and it may fairly be said to consist, as at contemplative ding so. While the gas-engines are running, the steam crowded with exhibits, and the manufacturers' representatives are busily engaged in explaining to the public the nature of the work exhibited by them. This is as it should be, but the great success, the guiding department were an aspect that suggests that the companies have either nothing to show from it, or are better employed elsewhere. Nevertheless, the date of our former notice a certain amount of progress has been made, and the Exhibition in its present form will probably be pronounced to the work to be done. The Vredenburgh has extended his installation by the fixing of seven additional arc lamps, mounted upon gilt lights, different types of machine are in operation. The Wallace-Farmer machine has now been in use for some time, and the Crompton machine has just arrived, Mr. Gilles' apparatus is fed by a steam engine, although it is capable of being worked electrically. The rest of the novel, and at present inscrutable machine, is exhibited by the Company. These incandescence lamps, arranged in parallel arc, and can which there are also a few Crooker incandescent lamps, are driven by a dynamo machine in the basement, in furnish a current that may be graduated to any desired extent. Court for a further display of the same commodity, although but little is actually completed. Prepartions are being made in the Eccle-docence. Among the other exhibitors there is Mr. Crompton, who has a number of his dynamo machines at work, and a machine has been fitted up in the nave where the experiment of handling the electric current may be made. In the Gallery system the incandescents are arranged in parallel circuit between the mains, and after the manner adopted in incandescence lamps, and consequently the difference of potential between the two conductors is only that corresponding to the electromotive force necessary to maintain an arc. By this arrangement arc and incandescent lamps may be burnt on the same circuit, if the resistances of the latter be not too great. In the central portion of this nave there hang six Brockie's new compensating lamps, exhibited by its Inventor, Electric Light Company, and fed from a Gramme generator in the basement. The lamps contain a device for automatically altering the regulating mechanism to compensate for the decrease in the resistance of the carbons as they burn. This is effected by changing the tension of the regulating spring. The transept opposite the high-level entrance, and a portion of the south nave, contain fourteen Gramme lamps, driven by a Siemens' alternate current machine, and a Gerard machine. In this latter, as our readers will remember, the field magnets revolve and the armature is stationary. Each coil of the latter is connected to an independent terminal, so that they can be grouped in any fashionable manner. A chamber in the Renaissance style, situated in the nave, is illuminated by ten Swinburne Pyke Main incandescence lamps, fed from a Gramme generator in the west corridor. This concludes the list of new exhibits in the department of electric lighting, added since our former notice. Unfortunately, they are nearly all well-known examples, and do not show that the progress has been made under precious share of last spring. In looking through the catalogue we come across many unfamiliar names, but the whole of them prove to be absent when sought for in the Palace. Perhaps these inventions were only in the paper stage when the Exhibition was projected, and have not yet got beyond it.

The preparations for the Electric Light Exhibition at the Westminster Aquarium have made substantial progress during the last fortnight. On Wednesday evening Messrs. Ferranti, Thompson, and Ince made a preliminary experiment with the current supplying the Grosvenor Gallery, and lighted a running gate into order. As this is their first appearance in the field of the great electrical illumination is therefore impossible to say. Time only will show whether the Aquarium is capable of being worked by the Ferranti machines with the same success as at the Grosvenor Gallery. The Edison method is complete installation, and the arch just in without mishap during the past week, and it is hoped that the machines will be ready for work by the end of the month. The Edison method is equally applicable to the Ferranti machines, and the Swan system is quite capable of being worked by the Ferranti machines. It has a wide driving pulley at each end of the axis, and on the centre-shaft there are two pulleys, each 5 ft. in diameter, and wide enough to take a 30-in. belt. If all manufactured belt-roads each liberal provision in the post we should have heard less of electric light failures. The lamps to be fed from this generator are situated in the swimming annex, and are 220 in number. The stand of Mr. Hiram Gibbs is also fully completed, and each day his system of electrical illumination is displayed. Owing to questions relating to his foreign patents we are unable to illustrate his apparatus at present, but we may explain that his object is to carry the electrical current through the gas-burning tube in the usual manner, and is to be utilised in the most economical form, that is to say, with the least waste of light-potential. Mr. Gibbs has also employed the electric current in the generation of other currents, whose intensity and quantity can be varied at will. The whole of the work to be done. The Swinburne-Pyke system is also represented in the Aquarium by a Gramme machine, which is fed from a common source, and permits that in town gas has been made, and the remainder inside the building. The installation has given great satisfaction; it was carried out by Messrs. Woodhouse and Rawson, of 11, Queen Victoria-street, London.

FEB. 16, 1883.] ENGINEERING. 155

FOREIGN TECHNICAL LITERATURE.

REVIEWING the work of the past year, the *Bulletin of the American Iron and Steel Association* (Philadelphia, January 3 and 10) remarks with regard to the iron building, that it appears to be slowly growing, notwithstanding a general impression to the contrary. The Delaware yards were busy, whilst those of Messrs. Cramp and Sons launched a tonnage of 18,331.

The Overland Summary (Calcutta, January 2) says that the Government of the Punjab intends to make a direct bridge in the coast-wrought iron between the Ravi canal and the railway, in the northern part of the Montgomery district. Two engineers have been employed to conduct the preliminary operations, and funds have been provided. The Ravi has formerly flowed through this district, and then it was fertile and thickly populated.

L'Industrie Belge (Brussels, January 21) contains an extract from the report of the Minister of Public Works with regard to the railways during 1881. The total length in operation on December 31 of that year was 2280 miles, 44 miles of which had been constructed during the year; 992 miles of the distance are worked by private companies, the remainder being by the Brussels and Rhine. The total amount expended by the States on the construction of the lines and their equipment was 41,580,320*l*., and the capital and the capitalised value of the annuities which the Government has to pay as the price of certain companies (which must be added to the above amount) 5,000,000*l*. The receipts of the State railways during the year were 2,028,320*l*., to which must be added a sum of 1,000,000*l*. paid by private lines on account of the use of working—including the 1,000,000*l*. All the above receipts had to pay the working expenses, which amounted to 1,353,240*l*. This, however, was not sufficient to meet the annuities due by the Treasury and the capital locked up in the payments to the companies whose lines had been purchased by the State, and the result was that the year's working showed a deficit of 228,105*l*.

The well-known Italian engineer, Sig. Garoia, contributes a long letter to the *Giornale del Genio Civile* (Rome, January 17), endeavouring to dispel the fears which have been entertained regarding the Mont Cenis tunnel. He is sure to the advantage of Fréjus that if the tunnel is to be pierced on that line, it will be the shortest of the three, and it is in order to enable their Atlantic ports to receive the international through traffic. The opening of the Gothard tunnel, and that if any part is injured by it, it will be Marseilles and not Genoa that will suffer. The opening of the tunnel would enable Frenchmen to the Lake to undersell English coal in the Italian markets, and would open the ports to powers that if the principal traffic over the Alpine lines is in trade between England and Belgium on the one hand, and Italy on the other; and that the international trade of England, which was expected to be largely increased by comparatively insignificant. He considers that the death of Mr. Gladstone would be a great blow to the Simplon project, of which he was a supporter, and that the probabilities are in favour of the Mont Blanc tunnel.

Army and Navy Journal (New York, January 13) publishes a table of the report made by the United States Naval Advisory Board to the Secretary of the Navy, on the system of defence during forts for monitors, designed by N. B. Clarke, Esq., of Washington. The report says that the monitors would require to be of which exhibits them to thorough experimental tests. The Board has been carried out the Board will soon give any recommendation for the adoption of the system. The report also declares that an appropriation of 50,000 dollars should be made for the purpose.

The Chief of the Bureau of Steam Engineering has prepared a report, showing the average speed per hour on the several vessels of the American Navy during its commission during the year 1882, when steaming at the ordinary current of service, and the consumption of coal per hour for each horse-power indicated. Of the 48 vessels commissioned in the year given, the average speed was 7·1 knots, while 26 vessels, with an aggregate of 37 lbs. of coal; four others above speed were 10 knots to the 1 knot, the coal consumed varying from 3·1 lb. to 4·9 lb.; and the remainder varying in speed from 8·3 knots to 9·5 knots per hour. The highest consumption of coal is that of the Minnesota, which required 7·2 lb. to attain a speed of 6·6 knots.

THE ELECTRIC LIGHTING ON H.M.S. "HIMALAYA."

DURING the conveyance of the army to and from Egypt, the government officials had considerable opportunities of observing the advantages to be obtained from the use of the electric light in troop ships. The *Orontes* was fitted, just before she sailed, with a large number of incandescence lamps in the men's quarters, in addition to those that she previously had in the saloon and staterooms. As the troops were carried in all parts of the vessel, even on the orlop deck, which of course receives no daylight at all, the superiority of the new light over the usual oil lamps was most marked, both as regards its greater brilliancy and freedom from heat and smell.

In the same way during the winter, tenders were asked for the erection and fitting of the troopship Himalaya, and the Swan United Electric Light Company obtained the contract, which was completed on December 17th last, in spite of considerable delay in the arrival of the machinery, which was expected in consequence of great trials and other work that was going on in the adjacent docks.

The installation consists of 121 lamps, each of twenty candle power, and 78, each of ten-candle power, fed by two Siemens' alternate current machines, with an ordinary large exciter. The armatures of each machine and the exciter are arranged upon the same shaft, so that the two may be driven together by a three-cylinder engine of the horizontal type, coupled direct to them. Each set of machines, with its engine, is mounted upon a carriage of its own, which is placed over an 8 in. teak keel firmly bolted to the framing of the ship.

The maximum speed of the generators is 640 revolutions per minute, but ordinarily they are run at 480 revolutions only, the following page we give four deck plans of the ship, showing the position occupied by the various parts of the installation, and by taking a portion of one of the deck beams adjacent to the engine-room, and enlarging it to 12 in. to 1 ft. (fig. 6).

The distribution of the lights through the ship is illustrated in the plans, while the principal fittings are shown in the detached views.

There are seven circuits, all of which are centralised from a main switch-board (Fig. 3) placed on the electrical-room, as shown in Fig. 2. From the latter seven branches or brass plates, numbered 6 to 12, each bearing the name of the part of the ship with which its respective leading wire communicates. Around this cluster of plates are arranged eight plates, 1 and 5, each provided with two set-screws for connection. At the upper part of the board are three plates, 2, 3, and 4, which 1 and 2 are connected to the generators, and are to the return circuit. Six cables, each of seven No. 16 B.W.G. wires, lead from the board to the various decks, and the current from the generators to the eight plates 4, 5, three to each, and four cables leading off to the detached lamps, and the return current from the plates 1, 3, back to the generators. Each of the cables that is led into lines to the left of the figure run from the plates 6 to 12 to the various parts of the ship, and are led in the same order to dotted lines, carry the return current to the plates 1.

All the parts are shown in the engraving all the circuit being disconnected from the generators, but if a wire be carried between plates 1 and 2 all the return leads will be connected with the latter, and by placing a plug between each of the plates 6 to 12 and the plate 4 will then connect the generators with the circuits, and the other terminals of the generators and one portion of the ship will be supplied with light. Each of the metal plugs on the board is large, and when all the circuits may be put in action. Similarly if a plug be inserted between plates 2 and 3 the return leads will be connected to the other generator, and the outward leads can be attached to the same or to several brass plugs of the left hand side of the board. If plugs be placed in both ends of a plate, as No. 5, the corresponding current would be coupled up to both generators, and would thus give double power. In case of a short circuit, the result would be quite satisfactory, as only that circuit would be put out of action, and the rest would be allowed to go on exactly as the same speed, the current being automatically cut off by the fusible wire.

The brasswork is secured down to a strong backing of vulcanised fibre, which is set in a teak moulding, supported by two iron brackets, arranged to suit the bend at an angle of about 30 degrees with the bulkhead. The grooved teak casing, in which the cables are placed in the electrical room, is brought up to and finished off at the switch board, which measures 18 in. by 8 in. over the screw-ends, and was manufactured by Messrs. C. Mayr and Co., of Liverpool.

The arrangement of the main switch board there are twelve plates, arranged to turn out all the lights except those which are in the cabins of the officers. Small switches from one or two lights are placed in all the cabins, and in any other parts where it is required to prevent the lights in detail, each small switch being provided with a lead cut-out. The main leads are of Siemens' Bullivan make, of nineteen wires of No. 16 B.W.G., heavily insulated with tape and india-rubber; the branch wires are a single No. 16 B.W.G., specially made for ship work by the Gutta Percha and India-rubber Company. The leads and returns are laid in grooved wood casings half an inch apart, and the greatest care has been taken throughout the ship to avoid any possibility of short circuits. Lead cut-outs are inserted at the junctions of all branch wires.

We give illustrations of three of the lamp fittings, which have been specially designed, and most of these supplied by Messrs. Faraday and Sons. In the saloon each light is placed in front of a mirror with bevelled

---

SWING BRIDGE AT HAMBURG.

We publish this week a two-page engraving, illustrating the arrangement of turning gear of the swing bridge over the Niederbaum Dock at Hamburg. In an early issue we shall publish further details and a complete description of the work.

LONDON ASSOCIATION OF FOREIGN ENGINEERS.—Sir James N. Douglass, C.E., has consented to preside at the Thirtieth Anniversary Festival of this society, to be held at the Cannon-street Hotel, on Saturday, April 21st, and he will be supported by Mr. Joseph Newton, C.E., past president, and others.

Engineering Feb. 2, 1883.

ELECTRIC LIGHTING NOTES.

THE system of street lighting by means of electric lamps erected upon high lattice poles or towers is extending rapidly in the United States. The towers employed are tapering skeleton frames, square or triangular in plan, built of iron tubes, united by special fittings of malleable iron, and terminated by diagonal struts and tie-rods. The towers are usually 160 ft. in height, and are hinged at the centre and also at their ends. The weight of the towers appears to vary considerably, and ranges from 100 to 250 lb. The cost also appears to depend upon the height and the proximity of the towers, but is usually two or three hundred times generally of the brush pattern. The local newspapers speak very highly of the success of the plan wherever it has been adopted, and say that it gives sufficient light when the towers are judiciously arranged to avoid shadows, for the ordinary purposes of walking and driving. The system seems hitherto to have been chiefly applied to Western towns, in which the street lighting was mainly confined to the central portion, the suburban and residential districts being devoid of artificial illumination, and this perhaps accounts for the somewhat florid descriptions that we have received of places in which the total amount of illumination, however distributed, was obviously insufficient according to English ideas. But it must be remembered that the amount of light required is largely dependent upon the state of the atmosphere, and that in this country a very large proportion is lost in the mist and fog that so often prevails. The same cause would also prevent our placing lights upon very high poles, because every fact of fog through which the light is projected quenches it, and consequently the higher the lamp the greater the fog and which no supernatural light would be practically useless. Whilst moderate ranges the plan of highly elevated lights has been tried in this country. In front of the Mansion House ten 50 ft. poles, each bearing a Gaulle power light, were erected, but it was found that the best results were obtained when the lamps were only hoisted 30 ft. Above this level too much of the light was shot over the neighbouring roofs. The Albert Dock at North Woolwich is illuminated for a length of one-and-a-half miles by 600 candle power lights raised 80 ft. above the ground, and the Holyhead Harbour has five lights, each of 6000 candle power, at the same elevation. The experiments gained in these and similar installations seems to show that from 50 to 60 ft. is the maximum height to electric lights in average English weather, and that although in exceptionally clear nights a greater elevation might be used, yet the American plan of suspending lighted elements intensely, such as the Brush lamps, 250 ft. above the pavement, would never be of practical utility in this country.

The preparations for the Electric Light Exhibition at the Westminster Aquarium are now proceeding very rapidly, and, although there is not much visible to the public, the heaviest part of the work is already accomplished. Three machinery annexes have been built on pieces of waste ground, and engines erected in them whose total indicated horse-power is 450, which it is proposed to increase to 550 if it should be found desirable. The first annexe, situated at the corner of the building the most remote from Westminster Abbey, contains one engine of 150 indicated horse-power by Davey Paxman and Co., one 90 indicated horse-power engine, by Hornsby and Son, and two 30 horse-power engines by the same makers, and is designed to receive another 90 indicated horse-power engine. There are already two Brush machines at work in this annexe, feeding 500 Swan lamps in the Imperial Theatre arranged partly in parallel arc and partly in series or three. The experience gained so far in this installation seems to show that the Brush machine is not well adapted for incandescence lighting. Active preparations are being made by the Jablochkoff Company, the Gulcher Company, Crompton and Co., Lane Fox, and the Swan Company for fixing generators in the second annexe. The second annexe lies at the north-east corner of the building and is allotted to Messrs. Ferranti, Thompson, and Ince, the Standard Fyfe Main Company, and the Edison Company. The power is derived from two Davey Paxman semi-portable engines, a Burkett caloric engine, and a gas-engine driven by Bowman and Co. The third annexe is under the smoking gallery, and contains the Siemens generator, by which the Aquarium has been lighted for some time past. In addition to this it has a 40-horse power Davey Paxman compound semi-portable engine of a new design, and is further intended to receive a number of Hadden's rotary engines. The total number of lights that will be in operation at the Aquarium, not counting dashlight premises, will be 2?4 arcs, and 2100 incandescence lamps, of which latter 500 are in the theatre. When the sun sets in Victoria he contrasted with that of the Palace, in Hyde Park, or of the Crystal Palace, it is evident that the Exhibition will equal, if it does not surpass in brilliancy any of its predecessors; and, as its central position and its nearness to the large railway terminal, under it for visitors accessible than Spitalfields. The catalogue of exhibitors shows an influential list of names, nearly all the leading manufacturers of electric light machinery being included. The Edison Company have secured a large display, the greater part of the gallery opposite the orchestra being allotted to them; it is being divided into courts, one of which will be filled with scientific objects illustrating the manufacture of electric lamps and generators; another shows the Edison lamp adapted to the illuminating of elaborately decorated interiors, while a third is being transformed by Messrs. Dick Radclyffe, and Co., into a beautiful grotto and palm-house. The Ferranti, Thompson, and Ince Company have secured the building in which the swimming exhibitions formerly took place, and will light it with 320 incandescence lights. As this is almost their first public display they are sure to attract much attention. The cave will be lighted by arc lamps of the Pilsen, Gulcher, Siemens, Gerard Lescuyer, and Patterson types, the luncheon gallery by Lorraine lamps, the reading room by 200 incandescence lights, the cellars and the ground floor by Jablochkoff candles, and the entrance by Standard Fyfe Main lamps. Edmundson and Co. are showing a large assortment of ornamental fittings, and are lighting two furnished rooms by Swan lamps. The space under the dining-room is allotted to the Pilsen Joel Company, and the smoking gallery to Messrs. Patterson and Cooper, who will erect there 200 incandescence lights. One curious feature of the Exhibition will be the market thereon the ground floor, which will be lighted by Swan lamps. Among the arcs there are four lamps shown by M. Lontin, and incandescence lamps and constant batteries by Messrs. Shipway and Coad, by Colonel F. Bolton, and by Mr. Dimm. The names we have mentioned by no means exhaust the list even of leading firms, but are sufficient to warrant the expectation that this long delayed Exhibition will prove a success at last. The only stand that appears to be complete at present is that of Mr. Dimm Gülke, who shows a new method of distributing electric energy, of which we shall have more to say in an early issue. Briefly it consists in using the main current to generate an induced current at the spot where it is required by means of an apparatus on the principle of the induction coil. By this means is it possible to work with a main current of high electromotive force, and to generate currents of various potentials according to the purpose for which they are required.

The general meeting of the Anglo-American Brush Electric Light Corporation terminated, as we announced last week, in an amendment being carried to the effect that a committee of shareholders should be appointed to consider and report upon the affairs of the company. It will now be remembered, and was fired for last Tuesday, at the noon time the directors issued a circular in which they declared their desire to court all possible investigation, but deprecating the publication of a report, which, however, was issued to the shareholders of the corporation. Having regard, they said, to the rival interests involved, the numerous companies with which the corporation has to transact business, and the complicated questions which were pending, and might at any time arise, between the corporation and others, the delicacy and difficulty of the task cast upon the committee would be obvious, and if any member should happen—as was the case with many who attended and voted at the recent meeting—to be interested in the companies owning concessions, or in rival companies having antagonistic interests, the injury that might result to the permanent interests of the corporation would, in the opinion of the directors, be vital, and possibly irreparable. They therefore determined to treat the result of the poll as an evidence of confidence, or the reverse, and if they were entitled to resign their positions at the earliest opportunity. In answer to some of the allegations made at the meeting, they said that, during the past six months, they had been engaged in perfecting the manufacture of a new class of economical machine for incandescence lighting, that of apparatus of various descriptions essential to the successful and economic lighting. On Tuesday last the votes were taken, and at the close the chairman moved a resolution adjourning the meeting until Monday, February 5, for the declaration of the numbers, and for concluding the business. It was stated by Mr. Braithwaite that the poll showed a large majority in favour of the directors.

During the festivities connected with the laying of the foundation stone of the infirmary at Cardiff and visiting the first set of the new dock, Lord Bute's castle has been lighted by nearly 200 Swan lamps with so successful a result that it is intended to convert them into a permanent installation. The whole arrangement was managed by Mr. W. T. Lewis, the marquis's chief agent, who retained Mr. W. H. Massey, of Twyford, to carry out the work.

ELECTRIC LIGHTING NOTES.

At the Friday evening opening lecture of this year's session at the Royal Institution, when Professor Tyndall addressed a crowded audience on "The Rainbow," the library was lighted by one of Mr. Rose's primary batteries. The hall of the Institution is now added to its own permanent installation, Messrs. Faraday and Son having supplied Grecian pendants, harmonising with the architecture.

The Committee of Inquiry appointed by the shareholders of the Metropolitan Brush Electric Lighting Company have filed a petition for the winding up of the company. In reply the directors have issued a circular to the shareholders, stating that this course is an entirely mistaken one, and affirming that their belief in the values of their numerous provisional orders is evidenced by the favourable proposals they have received for taking some of them over. The directors state that they have no doubt of being able, at the proper time, to make satisfactory disposals of their policy, which does not necessitate a call, as implied by the circular of the committee. For the present they merely advise the shareholders to refrain from signing any proxies, and from pledging themselves to any further action until they have seen, not only the report which the committee are about to issue, but also the reply of the directors thereto.

Messrs. Tangye Brothers have lighted their premises at Newcastle on the Swan system. The work was intrusted to the firm of Messrs. J. H. Holmes and Co., 67, Westgate-road, who have, with the exception of the engine and boiler, supplied and erected the whole of the machinery and apparatus required, and who have had most of the elaborate fittings specially manufactured to their own designs. The show-room has been fitted with four pendants, each of which carries five 20-candle-power Swan lamps and a reflector, so as to utilise the upward rays of light. Those in the front windows, being longer than the rest, have a novel and handsome form of reflector, the sides of the cells being of glass. The offices are lighted by ten lamps of the same power. The machine used is one of Siemens' self-lighting dynamos, and is capable of running forty 20-candle-power lamps when arranged in parallel circuit. The engine is of Messrs. Tangye's "Cubus" type, nominally 10 h.p., and of a "Cubicle" boiler, and when running the lights develop about 4 horse-power.

It will be within the recollection of many of our readers that twelve months ago Mr. Octavius C. Goode wrote a letter to the *Times*, in which he gave the particulars of the electric light installation at his house (Beechcroft Hall), and compared the system with that of gas. At that time the light had been in use for three months, and upon the data obtained during that period of working, Mr. Coope estimated that it would cost him 50*l.* or 4 farthings per burner per light. Now, after the lapse of a year, he has written again, comparing the actual expenses with the figures of his estimate, and he finds that his expectations have been more than realised, and that the actual cost per burner has been .35 of a farthing. The total cost of the installation was 1,400*l.*, and the year's expenses have been as follows:—Coals (small 13s. 6d. a ton, mixed with slack 18s. 9d. a ton), 27*l.* 14s.; wages (engineer and half boy), 78*l.* 14s.; interest on lamps (200 at 5s.) 75*l.*; oil, waste, &c., 3*l.*; repairs, &c., 5*l.* 14*s.*; sundries, 7*l.* 10*s.* 8*d.*; depreciation, 82*l.*; total, 279*l.* 18*s.* 8*d.* There are 200 lamps, and as they have been used for 4,224 hours, the cost works out to .35 farthing, as stated above. The plant consists of four Siemens dynamos, and a 12-horse engine. The lamps are mostly required singly, and in the hall and dining-room are hung by pendants from the ceilings by silk cords. Mr. Coope is quite enthusiastic in his praise of the healthfulness, safety, and economy of the lighting, but he does not make it quite clear how it is that the whole of the lamps were burning on an average five hours a day all the year round; the inference to be drawn from his letter is that every lamp was put in action at dusk and kept alight until nearly midnight, in all the rooms; so that the house was perfectly lighted all over, and darkness was abolished within it, until the engine stopped for the night. No doubt this is a very charming arrangement, and it is one that is peculiarly favourable to electric lighting, when estimated per lamp-hour; but it must be remembered that it is a very expensive one. A farthing per lamp-hour looks a very small sum, but 200*l.* per year for lighting a single country house is no amount not very often paid, we should imagine. We have pointed out again and again, that when an electric light plant can work at full capacity for 1500 hours a year, it may compete with gas, and that it is seldom that this condition can be fulfilled.

named officials of the deaths that ensued. 4. That the driver of the local special train which was late the standing train, did not keep a proper look out, and consequently failed to use the means at his command—the Westinghouse brake —to stop his train, and so avert the collision. 5. That the superintendent of the New York Central and Hudson River Railroad had failed to provide proper safeguards at the dangerous point where the accident occurred, and that he prescribed a dangerous rate of speed—twenty miles an hour—at a place where it was impossible to see more than 50 ft. ahead. Both these officials were also declared responsible for the deaths that occurred. Then we see that so far from the brake—which was found after the accident to be in good order—having caused this accident, it resulted from the foolish trick of a drunken passenger, followed by the thoughtlessness of the engine drivers, the neglect of the rear guard, and in a less degree to the want of care on the part of the driver of the train that ran into the one that was wrecked.

The jury also condemned the practice of placing it in the power of a passenger to stop a train by his own act, instead of merely announcing to the driver the necessity—real or imaginary—for stopping.

We are glad to see that the *New York Railroad Gazette* fully endorses the verdict of the jury.

A PHOTOGRAPHIC EXHIBITION.

During the last five or six years a new method of making negatives on glass has been gradually coming into use among amateurs; and, at the present time, this new method bids fair to soon render the old process with collodion and the silver bath a thing of the past. In the case of the ordinary wet collodion method a film is first coated with collodion containing soluble iodides and bromides, and when nearly dry is then immersed in a solution of silver nitrate, so that the sensitive mixture of insoluble silver iodide is formed in the film. The new gelatine-bromide method is different, a kind of wash being made of the sensitive salts and gelatine, and it is merely necessary to coat the glass plates, after which they are dried in a horizontal position. Such plates will keep indefinitely, and are consequently always ready for use in the most portable point of advantage in their extreme sensitiveness; in properly prepared, gelatine-bromide plates only requiring an exposure in the camera about one-twentieth as long as would be necessary in the case of a wet collodion film. Hence we now have not only any striking examples of rapid or so-called instantaneous photography—like that of a bird flying, alighting in full sail, machinery taken while in motion, and other similar subjects—but

Then circumstances, together with the ease with which the gelatine-bromide plates can be used, have united have tended to largely increase the scale of amateur photography, and to give it a great deal of general interest in the subject.

The Council of the Society of Arts have endeavoured to meet the requirements of the period by asking Captain Abney to deliver a course of Cantor lectures on Recent Advances in Photography, and Mr. Trueman Wood to give a course of the lectures by a technical exhibition bearing on photographic matters. In carrying out this idea Mr. Wood has received no small effection contributions. We are pleased to see that the literature of the gelatine-bromide process is not neglected, as side by side with an interesting series of exhibits showing the rapid advance of the new process we notice Dr. Eder's extensive work on "Modern Dry Plates," and the "Year Book of Photography;" this latter is be a comprehensive annual record of progress; both these works being issued in connexion with our contemporary the *Photographic News*. Those of our readers who take any interest in photography should not fail to visit this most important and complete exhibition, and we are told that tickets may be obtained by applying to the secretary of the Society of Arts.

THE WEATHER, JANUARY, 1882.

JANUARY has been dry and gloomy with an unprecedented prevalence of fog. At extreme positions of the British Isles, to which the Isle of Man is central, the mean atmospherical pressure and temperature were as tabulated above:

Atmospheric pressure has been uniformly above the average, and though the excess is remarkably high, still this distribution should theoretically be accompanied with normal winds. The resultant of the daily general directions of the winds is south-west by west, which is exactly the same as the normal resultant. In fact, there was very little

Positions.	Mean Pressure.	Difference from Normal.	Mean Temperature.	Difference from Normal.
	In.	In.	°	°
North ...	29.82	above 0.01	42	above 1
South ...	29.82	" 0.01	44	" 2
East ...	29.81	" .02	43	" 2
West ...	29.81	" .02	44	" 2
Central ...	29.81	" .02	43	" 2

cresting in the wind during the month. The temperature was above the normal, especially in the west and north. The distribution of rain may be inferred from the following statement:

Hants.	Rainy Days.	Amount.	Difference from Normal.
		In.	In.
Scarborough Head ...	25	3.25	above 0.25
Delft ...	16	2.00	below 0.25
Valentia	26	6.00	" 2.50
Portsmouth	17	2.50	" 0.50

The rainfall in the north seems to have exceeded the usual quantity, but elsewhere it was very deficient. The dryness is evidently related to the high barometric pressure, and the mildness to the south-westerly winds and the constant state of sky, which was unfavourable to radiation of heat from the ground or lower air. During the first week severe gales prevailed in the north. On the 6th a violent gale was attended with lightning and thunder for hours, and caused disastrous floods in Ayrshire. At Glasgow the wind had a pressure of 51 lb. to the square foot and a velocity of 80 miles per hour, about 1000 trees being uprooted anemometers. The fall of barometers was very rapid to 28.4 in. On the 18th the barometer stood nearly at 31 in.

During the latter half of the month, atmospheric pressure continued remarkably high, especially on the south and east of England. On the 25th the maximum temperature at Nottingham was 69 deg.; on the 26th at Oxford the minimum was 20 deg. A little snow fell in the north of England towards the end of the month. On the 1st, 1.20 in. of rain was measured at Valencia; on the 5th, 1.05 in. at Roches Point; and 0.93 in. at Selby on the 18th. Among the contrasts of simultaneous temperatures exposed surprising were the following: On the 16th, Nairn 54 deg., London 36 deg.; 17th, Sunburgh 50 deg., London 32 deg.; 18th, Nairn 51 deg., London 31 deg.; 19th, Sunburgh 48 deg., Nottingham 31 deg.; 24th, Stornoway 50 deg., London 31 deg.; 25th, Stornoway 50 deg., Oxford 25 deg. The instances of temperature in the most southerly west exceeding that in the east and south-east, are also very surprising, as the former have a maritime winter climate, and the latter rather a Continental. Bright sunshine was most frequent in the south-east, where, during the five weeks ending the 30th, 30 per cent. of the possible duration was registered, while south Ireland had 28 per cent., north-east England 27 per cent., north Ireland 26 per cent., south-west England 19 per cent., west Scotland and north-west England 11 per cent, and south England only 9 per cent.

By referring to the summary of the weather for January, 1881, it will be seen that the weather of the past month was quite a contrast to it, which may be illustrated by what happened on the 26th last year; barometer below 29 in., piercingly cold easterly gale, force reaching 75 lb., lids 5 ft. above due height at Westminster, deep fall of snow; this year, barometer 31 in., light airs from S.W., and dense fog. January, 1882, was about 11 deg. warmer than January, 1881.

THE MAXIM ELECTRIC LIGHT.

The Electrical Exhibition in Paris is already beginning to bear fruit, thanks to the combinations made by which some of the more important systems of electric lighting fall into the hands of powerful companies. It was in this way that the Compagnie Générale d'Electricité (which we believe is about to undergo a third change, by being formed into a new society with a capital of 75,000,000 francs) has recently under one larger arrangement, the Jablochkoff candle, the Jamin, Werdermann, and Heyder lamps, the Jarger regulator, the Maxim incandescence light, and the Gramme generator, so that it can now supply any system of illumination that may be desired, from the lamp of a few candle power,

ELECTRIC LIGHTING MISCELLANEA.

Engineering June 29 1888

Ten paper read by Mr. Esplin, of Forfar, before the North "not dependent." Seeing that it was the first time he had British Association of Gas Managers can scarcely be com- pact the shareholders under these circumstances, despondency mended. He was asked to contribute a paper; he did not would have been somewhat premature. Of course the Chair- know what to write upon; therefore he chose the electric- man had him at the Electric Lighting Act and the Man- light—presumably because he did not know much about it, chester Corporation. What Directors of lighting Electric and thought his colleagues knew less, and would consequently Lighting Companies would do for an excuse if they had not be interested in anything he could find to tell them on the the Board of Trade scapegoat, it is difficult to imagine. With subject. This was not a promising beginning; and it did not unanimously satisfactory the Chairman announced that the improve. Mr. Esplin had obtained one fact—that a manu- payment to the parent Company for the Manchester license facturer had tried Brush lighting in a certain department and had been reduced from £20,000 to £10,000. So far, good: a cost of £120 per annum as compared with £75 for gas; but it is too evident that fuel fasts justified their early hopes, leaving out the cost of motive power. This is a kind of the Directors would rather have paid the larger sum. When estimate, or rather of record, similar to that sometimes people accept £10,000 for something that was sold for heard of in regard to certain patented gas-making machines £50,000, it is evidently dear at any price.

used in mills and factories, when the cost of gas is always brought down to about eighteenpence per thousand cubic feet, by leaving out a few items which figure largely in Gas Companies' accounts. As though this statement were not sufficiently favourable to electricity, moreover, Mr. Esplin went on to cite one or two electricians' estimates for work not executed; which, of course, showed a saving as against gas. This was pushing magnanimity to excess, even for a gas manager when spending of electric lighting. It is regret- table also that the author should have repeated without question the oft-refuted assumption that Brush lamps give 2000 candles illuminating power. It is a relief to turn to the straightforward utterances of Mr. Smith, of Aberdeen, who at least spoke from his own knowledge. We can well believe that Mr. Smith, like Mr. Clare, of Blackpool, has done his best to make electric lighting successful. The result, however, is always the same—the boy will work if somebody sits up all night with it, and looks after it as he would a sick child. Otherwise there will be trouble, as people have everywhere found to their cost.

The Birmingham and Warwickshire (Brush) Electric Light- ing Company have held their second ordinary general meeting—in George Yard, Lombard Street. It is curious that this concern, which is nothing if not local, should not have been able to find a habitation in the scene of its sup- posed labours. This is only according to the fashion of many other country and district Brush Companies, whose practice is closely modelled on that of the celebrated Ethiopian minstrels who "never perform out of London." The mere fact of keeping the head-quarters of this particular Company out of Birmingham speaks for itself of the pros- pects of business in the town and district. Mr. G. M. Pelham presided over the meeting, and "expressed disappointment " at the results of the working." Of course he claimed, on behalf of the Company, to have sufficed merely from the action of the Legislature and the Board of Trade, "by which, " serious conditions had been imposed on them, and many " of the rights which they had thought they held had been " taken away from them." As to the former complaint, it is sufficiently justified by the Chairman's subsequent admission, that they had no money to make the deposit required for a Provisional Order. What prospect there might have been of the Company doing good work, if they are so short of capital as to be unable to find cash on money, the Chairman did not explain. It is rich also to read of the second complaint, when it is notorious that the electricians had no rights whatever before the Electric Lighting Act was passed, and therefore could not have lost anything by it. It is scarcely necessary to say there was no dividend, nor is there hope of any in future.

There is an Edison Company in Manchester, although their existence would never be suspected; and they have held their first general meeting. This was actually convened in the city whence the Company are named, and Mr. Y. K. Armitage presided. The Chairman, following the usual formula, regretted that the report and statement of accounts were not more satisfactory; but declared that at their next

ELECTRIC LIGHTING NOTES.

The British Electric Light Company has petitioned the Privy Council for a prolongation of the Grosnene Road, dated June 8, 1876.

The Edison Company is said to have 22,500 lamps in use on the Continent, of which 7000 are in Germany, 2200 in France, 4000 in Austro-Hungary, 3000 in Russia, and 2200 in Italy.

Messrs. William Penny Brothers, Lever Shipyard, Dumbarton, have added an electrical department to their extensive works, which will be completely lighted by electricity. Mr. R. B. Smillie, of Glasgow, has been placed in charge of the department.

The Committee of Underground Communication, New York, U.S.A., has examined 400 patents and designs relative to the question before them, but has not found a single one, any system which answers their re- quirements, if they seek a plan by which electric con- ductors of all kinds can be placed in the same under- ground pipe or channel, without injuriously influ- encing each other, and in such a manner that they may be easily accessible at all times.

The New Hotel de Ville, in Paris is lighted by Edison incandescence lamps, and is ventilated by fans driven by electro-motors of the Crompton type. The current is provided by two following systems, each furnishing from 175 to 200 horse-power, and absorbing about 30 horse-power. They are driven by two com- pound engines, constructed by MM. Weyher et Richemond, and situated, together with the boilers, in the basement of the building. The conductors from the machines are carried to a switchboard, from which three pairs of wires run, one to feed the lamps in the wing by the Rue de Rivoli, another to the towers surmounting the court of Louis XIV., and the third to the façade. All these circuits mount directly to the second story, and then circulate under the floors, passing through the ceiling of the first floor at the places where the lamps are situated. Each subsidiary circuit starts from a switchboard, a flexible cord-out being placed in each branch of it. The circuit around the court is divided into three, which serve three-sixths of the square; that of the façade into four, of which one feeds the remaining six of the court, as well as the vestibule and corridor of the council chamber. The three other branches go to switch- boards on the first floor.

Engineering June 29 1888.

ELECTRIC LIGHTING FOR STREETS.

To the Editors of ENGINEERING.

Sirs,—The subject heads which, for a considerable time, have appeared in your columns, and other papers, involving electric light companies to the supply of the light- ing of various thoroughfares within the City of London, and the comparative value of the last two years in the way of novelty or improvement of any note bearing upon electric lighting, I think should appear in leaflets that we have issued, which is the history when it is time to deal with, it as it is, are simply suggestive. I suggest a review of the whole question on a republished illustration. Of the incan- descent system, whatever may be the merits of the Edison, Swan, or Brush lamps, and the preserving hopes of its advocates to make it the general illuminant of the future, I think I am not expressing the general opinion when I say that, as regards street lighting, it is out of the question. Of the Brush system, which has received the public and street commissioners' favourable and liberal notice, adopted to maintain or increase its popularity, has failed to prove itself better than, or as cheap as gas, can hardly be sug- gested to replace it on the sole recommendation of its hygienic advantages, more particularly in open air places, needless to say, they are altogether inappre- ciable.

It is to the arc light companies, consequently, that we must look for the improved lighting of our streets for long and hotly asked for, and the task of rendering it, at all likely to compete for the privilege has become rela- tively easy; their number, since the unsatisfactory at- tempt of the first Company was to pay a rent for the whole at the rate of £300 per mile. The rights are all that charging the batteries, for the lighting was unsatisfactory, dear, probably, to local rates in the business, and is now discontinued.

During the past twelve months Mr. Haworth, Messrs. Simpson Brothers' resident agent in Manchester, has effected installations of the electric light in the Arkwright Arms Hotel, Hatton Garden, in the Union Inn, Newmarket, and in the Alexandra Theatre, Salford. The Duke of Edinburgh, Lyceum, Alexandra, Opera Comique, Prince of Wales, Savoy, Criterion, Empire, Gaiety, Globe, Royalty, Strand, Vaudeville, Standard, Shoreditch, Pavilion, Metropolitan, Princess's, Sadler's Wells, Surrey, Grand, Olympic, Novelty, Imperial, Court, Avenue, Prince of Wales, Trafalgar, Folly, Comedy, Toole's

The s.s. *City of Paris* has been very unfortunate in the matter of electric lighting. She was originally fitted with a Siemens W1 alternate current machine, an exciter, eight lamps, and an engine without a governor. Before she left the Mersey the engine ran away and severely damaged itself; it was replaced by a second, also without a governor. Ere the vessel reached *New York* a second running away occurred, this time the machine being destroyed by the excessive speed. When the ship returned home a new generator was placed in position, and a small governor added to the engine, and things went better until the governor was allowed to get out of order. Then, one day, when an officer in conducting a party of visitors round the ship extinguished a light by way of experiment, the increased speed threw off the belt of the driving pulley. The resistance of the main machine being thus considerably relieved, the engine again ran away and destroyed another armature. Since then the vessel has been placed in the hands of Messrs. Siemens Brothers to be fitted up according to their system. A powerful Hibbering governor has been added to the engine, and rope driving has been substituted in place of transmission by straps. In the forward engine room both exciter and generator are actuated by belts of the same rope, consequently a broken splice affects both equally.

An electric lighting plant for a cotton mill in one of the smaller Australian republics has just been supplied by Messrs. Siemens Brothers to a Manchester firm. It comprises seven arc lamps, 238 Swan high resistance lamps, one dynamo machine (8 D.), and one alternate current machine (W.). The whole has been so arranged that it can be put together on the spot by persons without any special knowledge. The general system adopted for the incandescence lights follows that in vogue in gas lighting establishments in this country. A channel will run lengthwise of the mill, replacing the usual gas pipe, just below the level of the ceiling, and at a point will depend from it carrying a lamp at a little about 6 ft. 3 in. from the floor. The main conductor lies in the channel, and a branch is brought from it down the pipe to each lamp. The parts of the channel and the pendants are clipped together so that the latter can be put on wherever required. The details of the installation have been designed by Messrs. Siemens Brothers' agent in Manchester.

Mr. Preece has been appointed to the Committee of Works of the St. George, Hanover-square, vestry, in the room of Mr. Spagnoletti, who resigned notice of the room is 120 ft. from the theatre and the lamps are Brush and Swan companies have been employed. The general terms of the report were opposed to the schemes of the companies, and a recommendation was added that the applications should be opposed. Similar objections were raised against the applications of the Metropolitan Electric Light and Power Company, for the parishes of St. Mary Abbot, Kensington, St. Pancras, Westminster, and St. Martin-in-the-Fields, and it was determined to insist upon extensive modifications in the terms of the provisional orders to protect the interests of the parishioners.

Mr. W. C. Glen, and Mr. A. Ellens have published a little book called "The Electric Lighting Act, 1882, and other Acts incorporated therewith, also the Rules of the Board of Trade, of October, 1882; with Introduction, Notes, and Index." The object of the book is to furnish those interested in public electric lighting with a knowledge of the legislative provisions laid down for their guidance. It comprises, in addition to the recent Act, those of the Gas Works Clauses Act, 1847; the Metropolis Management Act, 1855; the Tramways Act, 1870; the Gas Works Clauses Act, 1871; the Board of Trade Arbitration, &c., Act, 1874; the Public Health Act, 1875; the Local Loans Act, 1875; the Telegraph Act, 1878; and the rules of the Board of Trade (October, 1882). All these Acts are either partly incorporated with or referred to in the Electric Lighting Act, and need to be consulted as aids to the interpretation of some of its provisions; but with this help much most remarkable clearness and lucidity is illustrated what line of action will be followed by the Board of Trade, who have power to make rules aimed at their discretion. As an instance it may be cited that it cannot be determined from the Act whether more than one licence or provisional order can be granted for the same area, and, if not, what considerations will guide the authorities in enrolling out a district among the various applicants. In the case in point seven different companies have applied for power to light it, and as yet no one knows whether, subject to satisfactory guarantees, the Board of Trade is willing to divide it among them, or whether it will undertake the task of deciding which of the seven is best fitted to do the work. The critics of the book have added notes and cross references, where they seemed requisite or likely to be useful, and have given a copious index, so that the operation of one Act upon another may be easily followed.

Our contemporary *La Lumière Electrique* publishes an interesting letter from a correspondent, in which the lighting of the Alhambra Theatre, Havana, Cuba, on the Edison system is described. The number of lamps is 185, of which 162 are in the Carcel and 14 of two Carcels, or 3 and 12 candles. These have replaced 312 gas-burners, an excessive number rendered necessary by the inferior quality of the gas supplied; the difference of temperature within and without the theatre now and all conditions of lighting is 14 deg. Fahr. The lamps are arranged as follows:

Positights	Lamps.
Two feet low for lighting the stage, each 10 lamps	20 at 1 ,,
Two feet low for lighting the stage, each 6 lamps	12 at 1 ,,
Three rows of brackets round the three galleries, each having two lamps	72 at 1 ,,
Four brackets, each with four lamps on each side of the stage	16 at 1 ,,
Twenty-four brackets on the outer four corridors	24 at 1 ,,
Ten brackets in the boxes	10 at 1 ,,
Eight brackets in the vestibule	8 at 1 ,,
Three lamps in front of the theatre	3 at 2 ,,
Total	185

Besides these there are seven 10-candle lamps for lighting the machine-room, which contains two Edison generators, type No. 6, which are also to feed 60 lamps of two Carcels, or 120 of one Carcel each. They are driven by a 14-horse power engine. The machine-room is 120 ft. from the theatre and the lamps are from 50 ft. to 80 ft. to switchboard. The lamps are grouped in two separate circuits, one lighting the façade, vestibule, boxes, corridors, and one line of lamps round the house; the other, the other tiers, the stage, and vestibule, the last two being all the stage lights. This arrangement was employed in order that if an accident occurred to one of the generators the house should not be left in darkness. The conductors are taken from the machine-room across the street at a height of about 20 ft., the diameter of these conductors is 5.5 millimetres. In running the building the current is divided among a number of smaller conductors of 2.40, 2.77, 2.11, and 1.21 millimetres in diameter, and through fuses to the lamps. From an experience extending over eight months it has been found that the same duration of each lamp exceeds 800 hours. The cost of the installation did not exceed 8000*l.*, and the daily expenses are as follows:

	£	s.	d.
Anthracite coal (200 kilos.) at 47 Francs, a. d. to 50 Francs (20.) per ton	3.5s	7	2
Engineer	20	—21	0
Fireman	12.5s	16	0
Cleaning, oil, &c.	2.5s	2	0
	54.0	47	7.2

The yearly expenses are shown below:

	Francs.	£.
Deterioration of plant 10 per cent.	2,000	80
Interest on capital 10 per cent.	2,000	80
Renewal of lamps (average life, 800 hours = 225 hours of burning, the hours = 225 hours renewed 24 times a year), 550 lamps at 3.7 Francs (3s. 0.6d.)	1,965	74.6
Daily expenses, 365 days at 54.5 francs (2s. 7.3d.)	19,892	795.68
	25,757	1030.28

The total number of Carcel hours being 445,300, the total cost per Carcel hour—.0578 franc or .55d. The price charged by the Havana Gas Company is .0625 franc, or about .52d. per Carcel hour, this gas being of a very low quality, and badly purified. There is thus a marked economy in the use of the Incandescence lamps. It is worth noting that the cost of this installation was practically 200 francs, or 8*l.* per lamp. The enormous wages paid to engineers and firemen, the high price of coal, and the charge of 10 per cent. as interest on capital, are all features of interest in the foregoing estimate.

The following particulars of an English installation will form a very interesting comparison with the foregoing. In a letter to the *Times* Mr. Alexander E. Cooper gives some details of a plant laid down at his residence, Berenbrook Hall, three miles from Colchester. The extent of the installation was 200 Swan lamps of 18 candle power, and the cost was as follows:

	£	s.	d.
Four dynamo machines	495	0	
Engine, boiler, and belting	190	0	
Engine foundations, &c.	25	0	
Engine foundations, &c.	25	0	
,, and dynamo house	120	0	
200 Swan lamps	195	0	0
Sockets, cables, switches, &c. ...	70	0	
Erection, laying wires, &c.	90	0	
Chandeliers, brackets, &c.	283	18	
Cutting and making good walls, floors, &c.	60	0	
	1670	8	

This total is equivalent to nearly 7*l.* 8*s.* per lamp. The estimated cost for establishing gas at the same place was:

	£	s.	
Machinery, building, and erection ...	750	0	
Gas main to house	75	0	
Laying pipes in house	200	0	
Cutting and making good	50	0	
Chandeliers, brackets, &c.	258	0	
	1333	16	

It may be fairly assumed that the total cost, including unforeseen expenses, would have been about the same as for the electric light plant. Mr. Cooper gives the annual working expenses as follows, presuming that the lamps are worked 1150 hours in the year:

	£	s.	
Coal at 20*s.* per ton	34	10	
Engine driver, 30*s.* per week,... ...	78	0	
Lubricating oil, &c.	18	0	
Depreciation 10 per cent. on engine and boiler	19	0	
,, ,, on dynamos	71	0	
,, ,, on conductors	4	0	
Total	232	15	

To the above ought to be added 5 per cent. interest on the capital invested—7*l.* 10*s.*—bringing the total annual outlay to 240*l.* 5*s.* This, with 1150 hours in the year for each lamp, or 230,000 lamp-hours in all, brings the cost per lamp and per hour to .25*d.* Mr. Cooper estimates that to obtain the same light with gas at Berenbrook Hall would cost 400*l.*, which would be equivalent to a price of about 1*s.* per 1000, allowing that 6 ft. of gas per hour will yield one candle power, and 5 per cent. for depreciation. This appears high, but Mr. Cooper apparently speaks from no actual experience of consuming gas on his premises. At all events the price is in excess of that quoted by the manufacturers of such plant, what is guaranteed by the manufacturers of such plant,

Engineering, July 22, 1882.

ELECTRIC LIGHTING NOTES.

Last Friday an extraordinary meeting of the Swan United Electric Light Company was held to receive the approval of the shareholders of the Bill now before Parliament. It was thought that some difficulty might arise as to whether the united company could adopt the provisional orders which had been obtained by the two companies, and the object of the Bill was to prevent this. The chairman stated that all the business was now transferred to the Edison and Swan Company, and he believed they were selling their lamps fairly well, and making a profit.

Some very interesting electric lighting experiments are about to be made at Hastings, in relation to obtaining the best mode of lighting the fish streets. They will be conducted by Mr. Preece, and the trials are intended to determine the relative efficiency of arc and incandescence lighting, the proper distribution of the lamps, and the most economical and effective manner of diffusing the light. The engine and dynamos are in position. The experiments are independent of any system or interests, and are looked forward to with much scientific and public interest.

An important installation was inaugurated last Monday at the Bank of England, the directors of which instructed the executive of this work to the Electrical Power Storage Company, Limited, the manufacturers of the Crompton and Kapp dynamo accumulator. The installation has been fitted up without interfering with the work of the employés. Progress has necessarily been slow in consequence of the limited periods during which workmen could be employed. It was intended to take the motive power from the existing steam engine and boiler, and to work with Wood over forty accumulators, but it was subsequently found to be more convenient and perfectly safe to employ a small portable engine and boiler for the purpose. The Secretary's office of the Victoria type constructed by the Anglo-American Brush Electric Light Corporation. Its carbon resistance is 120 volts, and it is capable of giving a current of 60 ampères. The dynamo charges an accumulator of 55 Faure-Sellon Volckmar cells, which in turn feed 150 incandescent lamps like those now distributed throughout the private drawing office, the hall office, and the counter. The lamps have a rating of 20 candle-power. The installation is fitted through out with Ashmead's safety cut-out, which is employed so as to automatically break the circuit when a certain heat current is reached. The light and motive power are at present employed. The fittings have been manufactured by Messrs. Hart, Falk, and Company, the Storage Company, limited, and introduced through gear specified in such a manner as to permit the use of the dynamo for charging the accumulators without cutting out the one interfering with the other. The whole of the installation has been carried out under the personal supervision of Mr. F. Thornton, the works manager of the company.

A very complete and successful installation of the electric light has been carried out on the Brazilian Imperial railway between Pedro and Queluz. Messrs. Mawson, which has just left the Clyde, the builders being Messrs. James and George Thomson. It includes 20 Swan incandescence lamps, each of 16 candle-power, which are distributed throughout the passenger carriages, the state rooms, officers' cabins, and in the luggage, the engine room, and the tunnel, &c. The power is obtained from a Thomson-Houston dynamo machine which is driven by a Stevenson dynamo machine which is driven by a Stevenson dynamo machine which is driven by a Stevenson

power of about 600 candles each, but designed for working a shift of nine hours, including the night and the morning. Placed at a distance of fully 100 yards apart, the lamps are raised to a height of about 50 ft. from the level of the rails, and the poles from which they are suspended are 70ft. high. The current for the two lamps is obtained from a Crompton-Burgin dynamo, of the C type. It is considered most likely that the directors will very soon give orders for the central station at Glasgow being adapted throughout to the electric system of illumination, for hitherto the lighting by gas has been very inefficiently performed.

The magnificent but somewhat unfortunate screw steamer Austral, belonging to the Orient Line, and which lay sunk at the bottom of Sydney Harbour during a period of some three months, has just been entirely refitted by her builders, Messrs. John Elder and Co., Glasgow. As on the first occasion, the electric lighting arrangements were entrusted to Messrs. Siemens Brothers, and carried out for them by Mr. R. E. Crompton, C.E. Special provision has been made for lighting with oil lamps, recess reflectors being placed on the Siemens system of wiring. The Siemens dynamo machines are two in number, both of the Siemens alternating type and each capable of maintaining 200 Swan incandescence lamps of 20 candle-power. These machines are driven by two of Gwynne's vertical engines of 10 horse-power each, and capable of working up to 23 horse-power indicated, which is transmitted by an endless cotton rope in the manner first introduced by Mr. Haworth, and since extensively adopted by many other leading firms in the electric lighting industry. Both engines are fitted with Pickering's governors. The electric lighting extends to the whole of the ship. Every passenger cabin has its electric lamp; even the second-class and steerage portions of the steamer have not been overlooked in this respect; and the arrangements are such that the light may be turned on or off at pleasure by the passengers themselves. The installation has been laid down according to the general practice of Messrs. Siemens Brothers, the wires being carried on each of the large screw stanchions. All the lights are under control from fixed stations, and are turned off at a certain hour, with the exception of a number which are left in action all night in the passages and saloons. The night cabin leads also supply the captain's, officers', and engineers' rooms, the chief room, engine room, stokeholes, tunnel, refrigerator, and electric room, &c. Four powerful arc lamps, each of 2000 candle-power, are fitted up over the deck of the ship, so that they may be used when she is in port at night coaling or taking in or discharging cargo.

ELECTRIC LIGHTING FOR STREETS.

To the Editor of Engineering.

Sir,—I have read with interest the letters subject in your issue of the 25th ult., was sufficiently clear to elicit, if it deserved any notice at all, objections of a less ambiguous character than those of "Ayr and Irvine dissent," and the "Secretary of the Hammond Company," in your issues of the 1st and 8th inst. respectively.

I cited facts resulting from my observations of the working of the five systems selected for the practical experiments of "electric lighting for streets" in London, which any one was open to any one to verify, criticise, or contradict.

The former of your correspondents gives us the experience of a particular arc system—*the new arc*, no doubt, working somewhere; name of system and place not given. The latter tells us of an instance of fifty arc lamps only eight incandescent lights scattered over a surface of about a square mile, and of the trouble and expense of repairing in duplicate the provisional specification, the complete specification, and all drawings. Another detail pertaining to his much vaunted "simplification of procedure" likewise appears to have escaped his memory. The inventor, for whom all things have been made so easy, is required to furnish, in addition to his two complete specifications and two corresponding sets of drawings, a drawing illustrative of the feature or features of novelty constituting his invention. This drawing must be prepared, in a prescribed manner; it must not cover a space exceeding 16 square inches; and there must accompany it a concise explanatory statement on foolscap paper, legibly written or printed. In short, the poor inventor who wishes to have, *for 4l.*, "the protection which the State has awarded to his ingenuity," will find a splendid field for the exercise of that quality (not to mention the virtue, patience) in attempting to comply with the requirements of the simplified procedure for which he owes such a lasting debt of gratitude to the President of the Board of Trade. Seeing how much the applicant for a patent has to do, and how long it must, at least, take him to do it; if it becomes evident what little value Mr. Chamberlain places upon an inventor's time, when he tells him he can get a valid patent for *4l.*

Surely, after this, inventors ought to feel themselves highly favoured, besides being legally grateful. *Engineering* *Yours &c.*

THE BRUSH COMPANY.

The report just issued by the reorganised Board of the Brush Company may be summarised in the words of the military command "as you were." The history of the company during the last two years is fresh in the minds of our readers; after a splendid course of advertising, the directors sold the patent rights in the form of local licenses to unlucky syndicates, who, after floating subsidiary companies (what are they doing now?) found that such a defect might be cured, where ill sense in the claims. But Mr. Chamberlain, having, of course, the poor inventor's interest at heart, did not adopt this suggestion. On the other hand, however, care has been taken to provide in the law that every ground on which a patent might, at the commencement of the Act, be repulsed by *ante facies*, shall be available by way of defence to an action of infringement, and shall also be a ground of revocation. These are points out of which the President of the Board of Trade apparently did not try to make capital in his misleading speech at Birmingham. Nor is he reported to have explained to his audience, that whereas the Act states that the application for a patent must be accompanied by either a provisional or complete specification; the rules, framed by his department under the Act, cast upon the applicant the trouble and expense of prepar

The Committee of Investigation appointed to examine into the affairs of Messrs. Mudie's Library Company have issued a circular to the shareholders stating that an agreement has been made between them and the Board to provide for the liquidation of the company by three members of the committee acting in conjunction with Mr. Borrer and Mr. Tottenham. A claim will have to be made on all any rate upon the promoters for a very large amount, and the committee feel that, in order to enable them to negotiate with the promoters for a settlement of the claim, should the opportunity arise, it is necessary that should be invested in the liquidators a power to compromise. It may be found necessary to provide for the working out of the provisional orders by means of sub-companies.

An extraordinary meeting of the Jubbulcholl Electric Light and Power Company was held on Friday last to consider three resolutions relating to the winding up the company, (2) to appointing Mr. W. A. Spain as liquidator, and (3) conferring on the liquidator a general authority to transfer the undertaking to a new company when incorporated. The chairman said petition after petition had been lodged against them by creditors when they could not pay, owing to the shareholders not answering to the calls. The new company was to have had 120,000 in capital in 1l. shares, 40,000 ordinary, and 80,000 6 per cent. preference shares. The first issue was to consist of 40,000 shares, to be issued at par for 30,000l., and the remainder would be sold in fully paid-up shares, and the remainder in debentures and cash. The liabilities were passed.

On Wednesday last the third ordinary general meeting of the Anglo-American Brush Electric Light Corporation, Limited, was held at the Cannon-street Hotel. A special resolution was passed for the purpose of reducing both the paid-up and nominal capital by 5*l.* per share, or from 800,000*l.* to 400,000*l.* There has at present 16,720*l.* shares with 10*l.* paid thereon, 20,000 with 8*l.* paid on them, and 20,560 unallotted, leaving 43,280 shares with 5*l.* paid. It is to be reduced from 10*l.* to 5*l.* The effect of this will be to diminish the paid-up capital by 283,560*l.*, which amount has been lost or is unrepresented by available assets. The report goes into the cause of this loss at length. There is a sum of 31,052*l.* which was typical at the last balance-sheet as being due from Mr. Lane-Fox, but which has been much reduced by a composition. It will be remembered that in 1882 Mr. Lane-Fox undertook to repurchase from the Corporation for a sum of 50,000*l.*, his distribution patents, believing that the company owed him much more than that amount. The company, however, took a different view of their indebtedness, and subject to the existing sum of 50,000*l.* being reduced by decrees and purchases, Mr. Lane-Fox took back the patents. He further undertook to pay the Corporation 20 per cent. of any profits he might make up to the 31st December, 1884, and from the next the Corporation agreed to transfer to Mr. Lane-Fox 14,000*l.*, in shares in the Electrical Power Company, and to make in the same proportion 14,000*l.* of which they have a first claim on all his electrical patents. The value of the shares in the new company is taxed to 25,000*l.* It originally stood at 179,686*l.*, in December, 1882, 152,056*l.* was written off, and now a further decrease is to be made. The property and plant stood at 37,823*l.*, of which 9,000*l.* is written off. A sum of 31,052*l.* is written off as "liquidation of patents," and is the result of the liquidation and part relinquishment of sundry claims; the item also includes 7,000*l.* amount written off in respect of bad debts. There is an item of 10,658*l.* "written off book value of patents," representing the difference between the value of the stock as per survey, and the value according to the books, which is considered the basis for winding up. It is proposed to still further reduce the value of the shares by 5*l.* each, that is by 47,280*l.* The sum of 10,286*l.* has been set aside "as provision against the shares held by us," and (2) whether any further loss may occur in the value of the shares that may hereafter occur in the value of the shares will not affect the amount reserved available for winding up the result of the manufacturing operations." The report and the Corporation, under the new arrangement, is shown by the following statement (omitting shillings and pence):—

Dr.	£	£	Cr.	£
Capital		1,120,562	Patents	25,000
Less calls unpaid		1,225	Bond and bullfrogs	25,000
		1,119,337	Stock	47,190
Creditors		148,977	Debtors	10,000
Provision against claims		10,286	Cash	12,045
Advice			Patents	9,232
		39,266	Balance	99,000
			Deficiency	1,018
		255,305		255,305

Out half the directorate retired after the last meeting and their places were filled by Lord Thurlow, Mr. H. C. Gibbs, and Mr. Edward Woods. The recommended board appointed successors to the late general manager, secretary, and engineer, and then reorganised the system of book-keeping. They found a whole host of difficulties with the subsidiary companies, and were threatened with actions on all sides, but after long negotiations they succeeded in effecting amicable agreements in all cases. They made alterations in the clauses of those licenses which bound the holders to use French and Lane-Fox apparatus only, and they secured for themselves the right to supply apparatus in the territories of the sub-companies on paying the latter a royalty. They have gone into the incandescence light, and have brought the Schuckert dynamos and the Lane-Fox lamp to a high degree of perfection for the purpose, and now they intend to resume their old position, and instead of being exclusively manufacturers they are going again into the market, and are prepared to supply private consumers. The Scottish and Irish companies have been wound up and their affairs likewise have received the approval of the separation upon surrender of the shares held by it.

The directors contend that the money loss is no indication of the future prospects of the company, and that even with the present amount of business there is a prospect of dividends.

IMPERIAL STANDARD WIRE GAUGE.

On page 218 of our last volume we gave a copy of the resolutions of the new legal standard wire gauge, issued by the Board of Trade, and below we publish a Table drawn up by the Iron and Steel Wire Manufacturers' Association, showing the lengths, weights, and breaking strains of iron wire under the new rules which come into force on the 1st of March next.

IMPERIAL STANDARD WIRE GAUGE.

Table of Sizes, Weights, Lengths, and Breaking Strains of Iron Wire, issued by the Iron and Steel Wire Manufacturers' Association.

January 10, 1884.

METROPOLITAN SEWAGE DISCHARGE.

The first report of the Royal Commission on Metropolitan Sewage Discharge has been issued. It consists of 74 pages, and is signed by the Commissioners. The terms of the subjects laid before it. These are (1) the best means of preventing the sewage discharged into the Thames by the Metropolitan Board of Works, and (2) whether any still effects result from the present discharge, and if so what are remedies for such effects.

"1. That the works of the Metropolitan Board for the main drainage of the north side of London be completed on the lines of Barking Creek and Crossness have been carried out, and that the sewage matter be dealt with at present mainly in the same manner.

"2. That the storm overflows allow the occasional discharge into the river within the metropolis of considerable quantities of solid fecal matter accumulated in some of the sewers; but this has not caused, under present circumstances, serious damage or offence.

"3. That the storm overflows between the northern outfall sewer and Barking Creek, Crossness, and not, as was originally intended, through the pumped pipe intercepting relief sewers from the discharge.

"4. That the discharge of the sewage is in no case prevented during this whole year without any attempt to realise it, or otherwise by separating the solids as otherwise is at variance with the original intention and with the understanding in Parliament when the Act of 1854 was passed.

"5. That the discharge from the main outfalls becomes very widely distributed by the motion of the water both upand down the river, being traced in dry seasons through the metropolis and almost as high as Teddington; and that it oscillates for a long period before getting finally out to sea.

"6. That the effluent of the sewage by the land and sea water, aided by the agitation produced by the various motions in the river, effects a partial purification of the sewage by oxidation; and that this purification is carried further by the action of the sea-water on the sewage solids.

"7. That the sewage which becomes distributed to the land and to the lower portions of the river thus gradually acquires offensive properties. The limits above and below the outfall of the sewage within which these properties exist with the ordinary tidal conditions, but it may be stated that in general above Greenwich and below Gravesend the river does not afford ground for serious complaint.

"8. That between these limits the effects of the sewage discharge are more or less apparent at all times.

"9. That in dry seasons the dilution of the sewage is less, and the offensive effects are more marked.

"10. That it does not appear that the effects of the sewage discharge has had any seriously prejudicial effect on the general healthiness of the neighbouring districts, but that there is evidence of certain evil effects of a minor kind on the health of persons employed on the river, and that these may reasonably be anxiety on the subject for the future.

"11. That in hot and dry weather there is serious nuisance and inconvenience, extending over considerable distances both below and above the outfalls, from the foul state of the water consequent on the sewage discharge. That such is very offensive and the water is at times turbid.

"12. That foul mud, partly composed of sewage matter, accumulates at Crossness and elsewhere, and adheres to nets, anchors, and other objects used in the river.

"13. That coal-dredged near the outfalls, which used to be obtained in a pure state, is now found to be so much contaminated with sewage matter as to be unfit for consuming the bridges to go further away.

"14. That the sewage discharge is not at times in a state in which such an important highway to a great capital as the Thames should be kept.

"15. That in consequence of the sewage discharge fish have disappeared from the Thames above Crossness for 15 miles below and for a considerable distance above them.

"16. That there is some evidence that wells in the neighbourhood of the Thames are affected by the water in the river, and that the quality of the water of some has fallen due to the sewage, but it may be felt on that point.

"17. That there is no evidence of any injury to the navigation of the river by deposit from the sewage discharge, but that this discharge adds largely to the quantity of solids in suspension in the water, and so helps to cause deposit.

"18. That the evils and dangers are likely to increase with the future population in the districts drained.

"19. That it is desirable that there should be another "storm overflow" for the purpose of completing or preventing the evils and dangers resulting from the present discharge.

"20. That before we proceed to this further breach of existing rules and regulations we should have a complete scheme of the proposed new outfall, which should be submitted for the consideration of Parliament."

MANCHESTER STEAM USERS' ASSOCIATION.

At the monthly meeting of the Engineering Committee of the Manchester Steam Users' Association, held at the offices, 56, Mosley-street, Manchester, on Monday and Tuesday, January 28, Mr. Alderman Scholefield in the chair, Mr. Bailey, C.E., Bamford, C.E., Fletcher, and Mitchell, C.E., attending, from which we learn that the Board of Trade inquiry into the explosion of the steam vessel in the working of the Manchester Ship Canal, in March, 1882, which explosion resulted in the loss of 12 lives, has been completed and the Board of Trade experts state that the causes of the explosion have investigated and reported on 45 explosions, since the 25 persons were killed and 34 others injured. The report attributes the explosions to the following causes:—1, explosions, 3; 2, overheating of plates, 3; 3, defective safety valves, 5; 4, defective boilers, 4; 5, weak or defective rivets, 3; 6, shortage of water, 3; 7, overheating through shortage of water, 1; 8, defective safety valves being inoperative, 4; 9, killing 1 person, 1; 10, defective boiler seams, 2; 11, defective furnaces, 2; 12, killing 2 persons, 2; 13, explosions, 3; 14, explosions, 3; 15, explosions, 3; 16, explosions, 3; 17, explosions, 3; 18, explosions, 3; 19, explosions, 3; 20, explosions, 3; 21, explosions, 3; 22, explosions, 3; 23, explosions, 3; 24, explosions, 3; 25, explosions, 3;

handling in Paris

That the electric lighting has distributed over the city of Leeds, with which the Municipality have contracted for the supply of current, is the

lighted by the electric light. More than 100 forms with reflecting shades are employed, and the effect is very good. The installation has been carried out by Messrs. Holmes and Company, of Liverpool.

Notes.

A meeting of the Institution of Mechanical Engineers will be held on Friday evening, the 7th inst., when a paper on "Steam Engine Governors," by Professor Unwin, will be read and discussed.

The Wellington Club ball-room, Liverpool, is now lighted by the electric light. There are 100 Swan lamps, with reflecting shades, and the effect is very good. The installation has been carried out by Messrs. Holmes and Company, of Liverpool.

Next Monday evening, the 10th inst., at the Royal Institution, Albemarle-street, Piccadilly, Professor Dewar will commence a course of three lectures on "Recent Researches in Spectrum Analysis." The course will be illustrated by a lime-light engine furnished by Messrs. F. Darlot and Co., of Paris, and by experiments.

The Institution of Civil Engineers will meet on the 1st inst., when was read a paper on the "Electric Lighting of Glasgow," by Professor Jenkin, of the University of Glasgow, and Mr. Mavor, of the Glasgow Corporation Water Works. The author is Professor of Engineering in the University of Glasgow, and the installation was carried out by the Municipal Authorities of that city. There were eight arc lights and 25 incandescent lamps in use during the trials, which were made on the 20th and 21st of November, 1883.

which effective and electric lights are set up here, and as which lights may be easily seen from the Thames, and which, it is certainly that the area shall be well lighted, and that there would be considerable difficulty in drawing the line between the two systems. The Board of Trade would have to consider whether they would not be bound to carry out the letter of the law, and to compel the Municipal Authorities to light the whole area, or an adjustable line, which would be very difficult to draw. The Board of Trade would also have to consider these difficulties are evaded by the Municipal Authorities placing the lights on the north side of the river, and not on the south side, as at present. The matter of future electric lighting will be considered by the Board of Trade shortly.

HORIZONTAL ROBING MACHINE.

The accompanying illustration represents a horizontal robing machine, specially designed by the makers, Messrs. Krupp, of Essen, for the manufacture of steel tyres. The machine is shown in the act of forging a tyre, which is placed on the mandrel, and is being operated upon by the hammer. The mandrel is carried by a traversing carriage, which is moved backwards and forwards by means of a screw, as the tyre is being forged, so that the hammer may operate upon every part of the tyre. The mandrel is also capable of being rotated by means of a worm and worm wheel, which are driven by a steam engine, as shown in the illustration. The machine is capable of forging tyres of any diameter up to 6 ft. 6 in. and 2 ft. 6 in. wide.

(To be continued.)

plying current to 1200 lamps, and driven by Porter-Allen or Armington-Sims engines, and Babcock-Wilcox boilers. In August, 1883, the Edison Company made a contract with the communal administration for the lighting of the Theatre de la Scala, and immediately afterwards they commenced work in the interior of the theatre, and also at the station, where they erected two new dynamos and a fifth boiler. This was all completed towards the end of November last, when the theatre was lighted for the preparatory rehearsal days, and on December 21 the electric lighting was formally inaugurated.

The conductors are laid under the footpaths of the principal streets of the central portion of the town, in the neighbourhood of the Place du Dôme, and measure nearly 4 miles miles in total length. They extend to a distance of 1645 ft. in a straight line from the central station. The system supplies current not only to the Theatre de la Scala, but to also the Manzoni Theatre, and to a great number of private consumers, among whom there are three cafés, and many cafés, restaurants, and shops, particularly in the Place du Dôme and Galerie Victor Emmanuel. The number of lamps fed from the station is about 3200, and by the end of this month will have increased to more than 4000, as the wires are being rapidly extended to subscribers who have already contracted to take current. During the present summer it is intended to extend the system to other streets, increasing the number of dynamos to ten, sufficient to feed 10,000 lamps.

The contracts for furnishing light to consumers stipulate for various prices according to the consumption, upon the base of a constant sum for each lamp erected, to cover the interest and amortisation of the first cost, and as much per hour for the working expenses. Upon that plan large consumers have the electric light at a price about equal to, or rather less than, the price of gas, which costs at Milan 6s. 3d. to 8s. 4d. per 1000 ft., while small consumers, who burn their lights a less number of hours, pay ten to twenty per cent. more than for gas.

The Theatre de la Scala is the largest which has, as yet, been lighted by incandescence lamps. Under ordinary circumstances it is illuminated by 2500 lamps, of which 1000 are on the stage, which is the largest in the world, 410 in the auditorium and 500 in the vestibules, corridors, foyers, and boxes, and the rest in the offices, chauffeurs'-hall, staircase, cloak-room, pitching room, &c. The intensity of the light on the stage is 1200 lamps of 16-candle power. The installation, of which sight are for the nine floats, three for the battens, which number thirty-two, two for the foot-lights, and three for the great chandelier. These groups of lamps are controlled by twenty contact pieces corresponding to an equal number of degrees of illumination, from sixteen candles down to two. There are also four pendant regulators for the movable lighting apparatus, which can be placed at any part of the stage. These comprise six projectors, having in all ninety lamps, and twelve festoons of ten lamps each, designed to be laid on the boards to light the decorations from below. In every case the current is carried by conductors of stranded copper covered with India-rubber, and these are laid between the scenery, just as the ordinary flexible gas tubes are. All the lamp carriers are provided with red and blue glasses, in addition to transparent glasses for scenic effects. There are four main conductors carrying the theatre, which is at a mean distance of 1500 ft. from the station, and these conductors supply separately the stage, the auditorium, the vestibules, and foyers, and the extra scenic effects.

Besides the lamps already enumerated others are being erected for galas and *bal masqués*. They include 45 groups of five each in the auditorium, and 600 lamps on the stage. All the material of this immense installation has been constructed at the company's works at Milan, and in private manufactories, under the direction of Jacobi, Haskins, Gerard, Clerc, and Al. Guerini, and was sufficiently complete a few months before the rehearsals of the opera and ballet were ordered on December 21. At that date the new illuminant was viewed by the public, and received with the warmest acclamation.

Besides the central station, the Edison Company has numerous isolated ones in Italy, among which may be mentioned one of 1000 lamps at a cotton mill at Vendrì, with 500 lamps; one of 500 lamps at the Crespi spinning mill, and 300 lamps at the Nisalm weaving factory, besides others.

NOTES FROM THE UNITED STATES.

From Philadelphia, Feb. 22, 1884.

The American iron trade has not gained as much ground during the past week as the indications a short time ago seemed to promise. Inside selling prices to-day are 20 dols. for No. 1 foundry, ordinary, to 21.50 dols. for special makes; 18.50 dols. for ordinary No. 2 to 19.50 dols. for best. Of large sells in small lots at 17.50 dols., or makes at 19 dols.; very little sells above 19 few lots have brought 19.50 dols. The very investment of foundry and forge is for a slight increase in current requirements, about sufficient manifested by some about, although occasional inducements a the height of concession of about 25 Production is now at its lowest limits, as declined; a few weeks more of these or bring the iron trade to its turning point; demand is undoubtedly looked for by the watching the market the most closely higher prices will not be asked, quotations ably be even more firmly held than at occasional fermentation is likely to set in, provocation in effect by other furnaces Southern irons are selling at 16.50 dols., native, Charcoal liquor, 23 dols. to 50 bar, of fair makes, 32 dols. to 35 dols., and rial has sold at a little less. Common iron request at country mills, at about 1.75 cts., 1.85 to 2 cents; small lots from Merchant steel is in better requests, and are selling, and prices are very low; c active, and any upward tendency is out tion. Construction iron for car work, work, bridge work, and for ship and boat nearing its small lots at low prices. Cons nective that manufacturers are induced to concessions in order to attract as much sible. The rumour that steel rails would 28.50 dols. to 30 dols. is without foundation, a inside price for large lots at present, 30 dols., and in western mills 1 dol. to 2

ELECTRIC GOVERNORS.

To the Editors of Engineering.

Sir,—Surely Mr. Richardson deserves the credit of having invented all possible methods of "governing electricity," but only on the assumption that he be justified in saying that "Mr. Wilson's an infringement of his patent."

In the Provisional Specification, No. 5, A. D. 1, Andrew Jackson, from whom I have received a very letter on the subject, describes the idea appropriated followed up and published in his first specification.

But surely the idea of "governing the electricity" must have occurred to many, and if of an electro-magnet or solenoid directly to the engine would probably be the first method to itself.

But the difficulty lies in the practical application. The idea of a Chinese giant (or a dwarf) with an enormous wheel-barrow, and a child to control him is the first picture which presented itself when I myself, but he could hardly be that that combination was "essentially a principle" as the accountant more practical engineer, with a boy to drive, although I admit the saving the advantage of being more direct in Both solenoids and electro-magnets controlled by current lighting are not powerful enough to throttle valves, still less to actuate the cranks they must of necessity be placed on bridges main conductors, and must entail a loss of electrical the amount of which depends on the resistance and the electromotive force employed, as the resistance is constant, as it were, of series, it is consequently at some greater the actual work if it could be done directly economy in the production of the current.

Apart from the question of cost, a large saving made to work a small throttle valve direct, be a very large one, for the power available, valve pull on its cord, but only such a force to provide the maximum difference in electric pressure.

In the week any collision form of reversible solenoid direct is practically impossible, at *a fairly easy* if the solenoid's duty is merely a with some greater power. The solenoid is my governor, and I have only myself to blame that the friction of the plates was not overcome and the pull of the throttle valve changed.

The total amount of total pull to frictional resistance as 10 to 1, and the frictional power absorbed was rather less than half that of the electrical power developed.

But the friction of a throttle valve is nothing, working conditions, at any rate where shutting-down high-pressure steam are used, must be measured pounds, not in fractions of an ounce, and the total pull between frictional and electrical resistance is 1 retained. In fact, Mr. Richardson's governor must powerful, and should be more sensitive, than the ordinary governors with which it has to compete, and with electrical governors ought certainly to supersede.

Engineering, Feb. 24, 1884.

ELECTRIC LIGHTING NOTES.

THE Maxim-Weston Electric Company, Limited, have just completed an electric lighting installation for the new British Iron Company, Limited, who are, we believe, the first ironmasters in South Staffordshire to introduce the electric light. The light is installed in the mills and forges of their Congreaves Works at Cradley, near Birmingham, the current being supplied by a Weston dynamo to eleven Weston arc lamps and an estimated lighting power of 1600 candles each. The dynamo is driven by one of Messrs. Tangye's vertical engines of 16 nominal horse-power, having a 10 in. cylinder, and revolving at a speed of almost 150 revolutions per minute. The current is transmitted from a flywheel 48 in. in diameter, by means of a 7 in. leather belt, to a short length of shafting, carrying a wrought-iron pulley on which transmits the power to the dynamo by means of a 5 in. belt. The dynamo makes 1050 revolutions per minute when supplying the eleven lamps with a current having an electro-motive force of 280 volts, and an intensity of 19 amperes. With the arrangements made by the New British Company for the maintenance of, and attention to, the lamps, the light is expected to cost, at any rate, not more than 4*d.* per unit, and to give much better results—minimising waste, increasing production, and generally giving an improvement in the finished iron departments where it is located.

The s.s. Valetta, recently built by Messrs. Caird and Co., of Greenock, has been fitted throughout with the electric light by the Edison and Swan Company. The dynamos are two Edison L. machines, which have been altered to run at a slower speed—rather over 500 revolutions per minute—and sustain a somewhat larger number of lights than the normal number, by the strengthening of the magnetic field and certain other modifications. They are each capable of sustaining 200 incandescence lamps of 16 candle-power actual; it is only for a short time during the evening—when all the lights are burning, amounting to about 300, as reported at once—that it is necessary to run both machines at the same time. They are driven by a pair of vertical engines running at 270 revolutions per minute, made by Messrs. J. and H. Dewrance, of Hammersmith, and geared by means of an unoiled cotton rope, which runs three round pulleys provided with ten LJ grooves, the last turn being guided back to the proper groove by a pair of small guide pulleys. This arrangement was first introduced by Messrs. Siemens Brothers; it works very successfully, and is free from liability to break down, besides throwing very little strain on the engines. The dynamos are placed on sliding rails, and by means of screws can be moved forward to compensate for the stretching of the rope. The saloon is fitted with two rows of handsome gilded two-light pendants hung over the tables. The state rooms are lighted from lanterns let into the bulkhead, which also throw a light into the alley-ways, and are made to carry a candle as well as an incandescence lamp, the engine-room, stokehold, and the various officers' quarters, and forecastle, &c., are all supplied with substantial fittings, and are well lighted throughout. The wiring is, as usual in all installations made by the Edison and Swan Company on board ship, run in wood mouldings securely separating the leads one from the other, all main and branch circuits being fitted with fusible plugs. Where necessary, individual lamps are controlled by switches on the sockets, and a substantial switch board is placed in the dynamo room, to which are led the six circuits into which the wiring is divided. These are so arranged that by changing the plugs any circuit may be connected up to either dynamo. During the stay of the Valetta in London previous to her departure for her first voyage to Australia, the light was frequently exhibited to the visitors whom the Peninsular and Oriental Company invited on board. The entire absence of perceptible noise from the machinery was noticed as a very important feature of the installation, one of the most recent and best examples of the application of the electric light to steamships.

As might have been expected, the bold and trenchant policy of the Anglo-American Brush Corporation is being followed by other electric lighting companies, which, drifting fast on to the rocks of bankruptcy, can only hope to avert destruction by throwing overboard all superfluous cargo, and here and there a Jonah whose presence is likely to sink the ship. By doing this some of the associations may weather the storm, and hope yet to make a fair coast and prosperous voyage, but we must look to see the loss of many a good ship ridden on the rocks aforesaid, which, at least they will serve as a warning and land-mark to future adventurers. It is the Gulcher Company that has been adopting a policy of vigorous retrenchment. This company was established on the 1st of May, 1882, with a capital of 200,000*l.* in 40,000 shares of 5*l.* each, Mr. Gulcher and Mr. Grath had sold these patents to Mr. S. A. Hamilton for 20,000*l.*, of which 10,000*l.* was in cash and 20,000*l.* in shares. Besides these patents Mr. Crookes for incandescence lamps were bought for about 22,000*l.* in fully-paid shares. Mr. Hamilton sold to the Gulcher Company, his rights for 45,000*l.*, being 25,000*l.* in cash and 15,000 fully-paid shares. It is, first, the foregoing statements are shown on the face of the Registrar of Joint Stock Companies. However, from the company's report read at a meeting of the shareholders on Tuesday last, it appears that the actual capital consisted of :—

	£ s. d.
10,000 fully paid shares of 5*l.* each	= 50,000 0 0
30,000 shares on which 5*s.* 10*d.* has been called	= 29,906 10 0
Total capital	= 79,906 10 0

It is now proposed to cut down this capital to 50,754*l.* 10*s.* The condition of the company was such in September last, three special committees were appointed for investigation, for Financial, Patent, and Works. According to the reports of these committees, also was the condition of the company, and of course, the remedies to be applied. But the dark cloud had a silver, or at least a Britannia metal lining. Like the moon in the parable, the company had fallen among thieves—but into deep distress, and was lying helpless and all but insensible. But no harrier passed by, as Batterers, only good Samaritans, the very best of good Samaritans, these thieves came to the rescue, rescued up the company's wounds, and set it on its legs more than this they have forgiven large shares, and with a generous impulse too often inconsistent with commercial instinct. As time : The directors had actually received 70,000*l.*, of which 50,000*l.* were in fully paid-up shares, 20000*l.* in cash, and 18,000*l.* in shares on which 2*l.* 10*s.* per share had been (nominally we presume) paid up. The value of this large amount the promoters now proceed to the company including the 20000*l.* in cash, and ask for nothing in return save that the company undertakes to press them for the 5*l.* per share due on their partly paid-up shares aforesaid. But generosity has its limits, and the promoters had paid a call of 10*s.* per share or 6000*l.*, and further, as they had incurred the expenses of bringing out the company, they are now to receive fully paid-up shares amounting in nominal value to 7000*l.* Possibly some of the ungrateful stockholders might have preferred that the promoters should have been content with the remaining 3*l.* due on their shares, under the call for 30,000*l.* in cash would be useful, but this it would have been unreasonable. In the same spirit, the Messrs. Gulcher, Grath, and Crooker consent to waive their claims, or rather to allow the number of fully paid-up shares which they had received in part payment for their respective patents to be reduced, until they shall bear the same proportion to the general capital after the cutting away of the promoters' shares, as they did before that operation. This being done, the amount paid for the patents will be 40,000*l.* instead of 110,000*l.* The Finance Committee made a sad discovery in the course of their investigations. On October last a bill of sale for 11,000*l.* had been given, covered by the whole available assets of the company, for a fifth call, which was payable on the 29th of October, and all arrears of call were nominally to one creditor, and, but funds in hand were insufficient to pay that debt, while a sum of 10000*l.* placed to credit in Jones turned out to be a liability in October.

Further calls on the shareholders put over three difficulties, but did not remove a new one. The operations of the Gulcher Company were (must not) carried on in works at Battersea, leased by Messrs. Bunsome and Co., of Chelsea, for a rental of 1000*l.* a year, and by an agreement with Messrs. Bunsome, the latter firm were to receive a commission of between 4 and 5 per cent. on the whole turnover of the company during five years. Now when the "intolerable character of the burden of such a commission" was represented to Messrs. Bunsome and Co., the firm acted with a generosity which throws that of the promoters and patentees far into the shade. They at once abandoned their whole claim, and not only reduced the rent of their tenants to 400*l.*, and the only thing they asked in return was that the Stanley Works Company, Bunsome and Co.) should be lighted on the Gulcher system during one year. In other words, not content with making these concessions, their sole profits in the embarrassed company, they advertise for the most economical mode of lighting, and the excellence of their very admirable system. Then, too, Mr. Crookes, the electrician of the company, has given up, or rather postponed, for the present his salary of 625*l.* a year, until the company's new association can bear the charge. As for the third report, we need only say that the Works Committee appear to have introduced many of the fundamental requirements for the proper carrying on of business, which were absent before the time of the special capital consisted of :—

	£ s. d.
10,000 fully paid shares of 5*l.* each	= 50,000 0 0
30,000 shares on which 5*s.* 10*d.* has been called	= 29,906 10 0
Total capital	= 79,906 10 0

It is now proposed to cut down this capital to 50,754*l.* 10*s.* The condition of the company was such in September last, three special committees were appointed for investigation, for Financial, Patent, and Works. According to the reports of these committees, also was the condition of the company, and of course, the remedies to be applied. But the dark cloud had a silver, or at least a Britannia metal lining. Like the moon in the parable, the company had fallen among thieves—but into deep distress, and was lying helpless and all but insensible. But no harrier passed by, as Batterers, only good Samaritans, the very best of good Samaritans, these thieves came to the rescue, rescued up the company's wounds, and set it on its legs more than this they have forgiven large shares, and with a generous impulse too often inconsistent with commercial instinct. As time : The directors had actually received 70,000*l.*, of which 50,000*l.* were in fully paid-up shares, 20000*l.* in cash, and 18,000*l.* in shares on which 2*l.* 10*s.* per share had been (nominally we presume) paid up. The value of this large amount the promoters now proceed to the company including the 20000*l.* in cash, and ask for nothing in return save that the company undertakes to press them for the 5*l.* per share due on their partly paid-up shares aforesaid. But generosity has its limits, and the promoters had paid a call of 10*s.* per share or 6000*l.*, and further, as they had incurred the expenses of bringing out the company, they are now to receive fully paid-up shares amounting in nominal value to 7000*l.* Possibly some of the ungrateful stockholders might have preferred that the promoters should have been content with the remaining 3*l.* due on their shares, under the call for 30,000*l.* in cash would be useful, but this it would have been unreasonable. In the same spirit, the Messrs. Gulcher, Grath, and Crooker consent to waive their claims, or rather to allow the number of fully paid-up shares which they had received in part payment for their respective patents to be reduced, until they shall bear the same proportion to the general capital after the cutting away of the promoters' shares, as they did before that operation. This being done, the amount paid for the patents will be 40,000*l.* instead of 110,000*l.* The Finance Committee made a sad discovery in the course of their investigations. On October last a bill of sale for 11,000*l.* had been given, covered by the whole available assets of the company, for a fifth call, which was payable on the 29th of October, and all arrears of call were nominally to one creditor, and, but funds in hand were insufficient to pay that debt, while a sum of 10000*l.* placed to credit in Jones turned out to be a liability in October.

The London Daily Chronicle, Nov 6, 1882

PUBLIC COMPANIES.

BRUSH MIDLAND ELECTRIC LIGHT AND POWER.

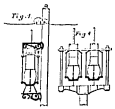
An extraordinary general meeting of this company was held yesterday, at the Caledonian Hotel, No. 3, St. Giles in the-field.

Mr. Cockburn (the chairman) said that the circumstances which led to the necessary consequences of several shareholders, whose holdings were of small amounts, having summoned a meeting of the company to recover the money paid on their shares on account that the statements in the prospectus as to the advantages which the company having the sole and exclusive right of the Lane-Fox patents would enjoy were not borne out by the documents before over by the company. With very little delay, a petition was written, a petition had been signed, and presented to the Chancery Court, and the result was that the provisional committee was not altogether so pleased. Certain small shareholders, representing 10 out of a body of over 200, and representing 10 shares, had taken advantage of what they considered the misstatement in the prospectus to bring serious pressure to bear on the future of their money. Some of the shareholders had been under the impression that a petition had been filed in Chancery to wind up the company, but this petition was quite of a friendly character, and it was only presented to protect the large shareholders against these small shareholders who were in a position to embarrass the undertaking. The misstatement upon which they founded their claim was that the prospectus stated the concession to be for the whole of the United Kingdom, whereas it had been ascertained that this was not absolutely the case, and that a company had not been injured in the event of obtaining or having the exclusive use of that lamp. They had therefore come to the conclusion that they could not carry on the business of the company profitably to obtain a all the Lane-Fox patents, and that they had been able to secure the rights for the whole of the United Kingdom, with the exception of Ireland. The word "exclusive" was used, but the error was quite a technical one, and of no practical importance to the company, as although the company had only been in existence a little more than six months, it had already been at work only for months, and had done a very good business, and had already got a large amount of outstanding accounts which would be coming in, and therefore he thought that the liquidators would be able to pay 20*s.* in the pound on the 5*l.* shares. Gentlemen who are fighting with very great success. Their district was mainly one of small towns, and of course the company was supplied with the small motor to provide the light much cheaper than they could have done if they would have to provide the motive power. They had not very well turned out Nottingham, where they had not very good premises, and where they had also to contend with the fact that the town gas had no less than five contracts. They had also to contend with Leicestershire, as at Chester, one as Stockport, and one at Nottingham. These companies were all in a flourishing condition. Of course, they had not been at work, as that the company was doing very well indeed, and that the very prospect of a very successful future for it. He moved—"That this meeting having heard the statement of the chairman as to the position of the company is of opinion that the business of the company can be carried on profitably, and that the proceedings of the shareholders who have demanded the return of their money, and therefore requests the directors to arrange with Mr. Wigram for the immediate withdrawal of his petition."

The resolution was seconded by Mr. Braithwaite, and carried with one dissentient.

The usual votes to the chairman and directors concluded the proceedings.

cooling 2.35 pence.* From experience obtained at other installations where they have more economical steam engines at work, Messrs. Crompton hope to reduce the



coal consumption on the Crompton arc light from 1.26 pence to .51 pence, which is the cost for coals for lights of equal size at King's Cross, and that for the Weston area from .54 pence to .26 pence.

TABLE I.—*The Electric Light at Norwich. Particulars of Horse Power absorbed.*

	H.P. at Horse Power as calculated from Indicator Cards.	Horse Power absorbed by Dynamo.	Horse Power absorbed by Shafting.	Horse Power absorbed by Lamps.	Arc Lights Crompton 2 Horse Power Lamps.	Arc Lights Weston 2 Horse Power Lamps.	Arc Lights Crompton 1 Horse Power Lamps.	Arc Lights Weston 1 Horse Power Lamps.	Arc Lights Crompton 1/2 Horse Power Lamps.	Arc Lights Weston 1/2 Horse Power Lamps.	Arc Lights Crompton Small Size Lamps.	Arc Lights Weston Small Size Lamps.	Incandescent Lights.
Engine unloaded	11.04	10.24	1.39										
Total, shafting and 11 dec. dynamos	11.81	10.24	1.39										
Arc lights in Prince of Wales'-road, brother to Market-place, Hall-plain, driving 7 Weston and Princes Street, Crompton, and 2 Crompton arc market lights	10.37	10.24	1.39	8.98				0.98					
Arc lights in Prince of Wales'-road, Princes Street, and 2 Crompton arc market lights	11.04	10.24	1.39	8.98		—		0.98		—			
Arc lights in Prince of Wales'-road, Princes Street, and 2 Crompton arc Market-place, 2 Weston arc Hall-plain, and 10 Swan incandescent lights	10.8	10.24	1.39	8.98	6.62	0.62	0.81	1.85	1.5				

TABLE II.—*The Electric Light at Norwich. Details of Working Expenses.*

	Horse Power used.	Coals per Hour.	Cost of Coals per Hour.	Coals per Horse Power per Hour.	Cost of Coals per Horse Power per Hour.	Cost of Water per Hour at 2s. 6d. per 100 gallons.	Cost of Oil, Waste, and Sundries per Hour.	Cost of Wages per Hour.	Total Cost per Hour.	Total Cost per Hour, in Pence.
	H.	lbs.	£ s. d.	lbs.	d.	£ s. d.	£ s. d.	£ s. d.	£ s. d.	d.
For each Crompton arc light	6.56	3.94	—	1.26	.51	.21	.52	.37	1.10	2.35
For each Weston arc light	1.79	1.34	—	.454	.183	.15	.157	.37	0.82	1.75
Total	15.8	10.8	1.17	0.75	0.306	1.36	1.2	0.42	1.4	0.716

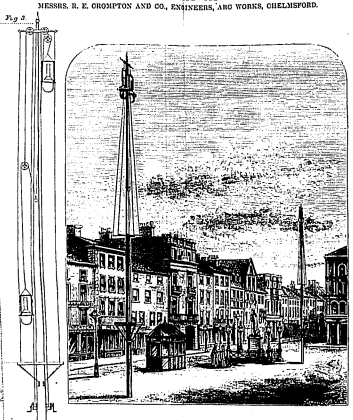
Under these conditions Messrs. Crompton think that the forty lights will not cost more than 5s. per hour, or at the rate of 1.26 pence per hour for the Crompton arcs, and 0.54 for the Weston arcs.

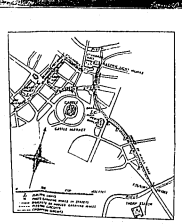
These Tables point out very conclusively that any considerable saving is to be looked for in these installations must be chiefly sought in the steam engine, and in the reduction of the coal bill. Some slight saving in improvement in the dynamo machines and lamps will have a but slight effect in reducing working costs. For instance,

* It is intended shortly to increase this Norwich installation to a total of 1,000 incandescence and thirty Weston arcs, and as the cost of superintendence and interest will remain nearly fixed, the working cost will be greatly lessened.

THE ELECTRIC LIGHT AT NORWICH.

MESSRS. R. E. CROMPTON AND CO., ENGINEERS, ARC WORKS, CHELMSFORD.





if a steam engine using but 2 lbs. per hour per natural horse power were put in, it would effect the reduction of 10 pence in the two items of 14.75 pence for coal and water. A reduction of carbon rods to one penny a foot would effect a saving of 2½d. on that item, the combined saving reducing the total cost from 40 pence to 25 pence. The wires are throughout No. 8 B.W.G. bare copper

wire carried overhead in a most substantial manner, on strong Stanton telegraph posts, and insulated in the usual way by earthenware insulators carried on oak cross pieces.

In Lesser-street, there are no poles, the wires being carried on east-iron brackets of ornamental design, bolted on to the fronts of the houses; some of the lamps in London-street are carried on the same brackets. The arc lamps are throughout arranged in pairs so that if any lamp fails to burn properly, or when its carbons are burned out the second lamp is automatically switched into circuit so that there is no interruption in the lighting.

The almost wasteful brilliance of the Haymarket, Market-place, Hall Plain, and Post-Office Plain has been of service in a somewhat unexpected manner. These open spaces in their former imperfectly lighted condition were the favourite resorts of the itinerant and homeless, and other disreputable characters. The police assert that since the introduction of the electric light it is a comparatively easy task to keep the pavements at the above points clear and orderly.

At before stated Messrs. Crompton now contemplate extensively adding to their plant, and supplement the public lighting by hiring out the current for incandescent lamps to all such consumers who care to use it within the area covered by their conducting wires.

The accompanying engravings show the general aspect of the works of the installation, and details of the light posts and the mode of suspension of the large Crompton lamp, as well as that adopted for the lower and smaller Weston regulators.

Engineering, April 7th 1882.

ELECTRIC LIGHTING NOTES.

THE Maxim-Weston Electric Company have contracted with the Science and Art Department to light the Bethnal Green Museum. They are furnishing the electric light at the Silbury Dock Works to enable the work to be prosecuted continuously day and night.

The library and dining-room of the House of Commons is now lighted by the Edison Electric Light Company with 265 incandescence lamps; three more being used in the engine-room. The power is derived from one of Armington and Sims' steam engines of thirty horse-power, fixed near the ventilation works, and conveniently remote from the boiler of the works. A cable of 1,000 ft. in length runs from the engine-room to the library and dining-room, where branch wires go to the clusters of lamps. Each clusterlier is kept under perfect control by means of a switch within the cupboard, and any lamps can be turned off without affecting the rest. The lights are partially turned down at midnight. The contract for the lighting extends to the end of the present session of Parliament.

At the forthcoming electrical exhibition in Vienna there is to be a pavilion specially constructed according to the wishes of the Emperor of Austria, and designed to show the effect of the electric light on clothe and broideries. Different systems will be exhibited. The Academy of Painting and Sculpture at Berlin has been lighted by 200 Edison lamps, and the dynamo is driven by a 30-horse-power engine of sixteen horse-power. At Budapesth, the capital of Hungary, the National Theatre is to be lighted by 1,000 Swan lamps. The Theatre of Rome, the Scala, has been lighted for several months by Edison lamps. The Municipality of Moscow has voted a sum of 30,000 roubles for the illuminations on the occasion of the Czar's coronation in May. The roof of the Kremlin, the ancient residence of the Czars, will be lighted with 69 electric lamps, each of 400-candle power.

The Gulcher Electric Light and Power Company, Limited, have been for some time settled in commodious premises in Battersea, adjacent to Messrs. A. Ransome and Co.'s foundry, and are actively proceeding the manufacture of their dynamo and arc lamps, and the Crookes incandescence lamp, of which they have acquired the patents. As our readers will remember, the Gulcher generator has an armature of disc form, and like a Pacinotti ring, and rotating through four U-shaped pole-pieces, alternately presenting north and south poles. The machine may now be made in six sizes, of which the smallest, No. 1, is capable of feeding four arc lamps of 450 actual candle-power, or two lamps of 1000 candle-power, or one of 2000 candle-power, or 20 incandescence lamps of 20 candle-power each. The largest machine, No. 6, with feet 128, or 64, or 32 arc lamps of 450, 1000, or 2000 candle-power respectively, or 640 incandescence lamps of 20 candle-power each. The characteristic feature of the Gulcher system is that all the lamps, whether arc or incandescence, are burnt upon parallel circuits, hence the two may be fed from one machine without any special arrangement, so long as both are designed for the same electro-motive force. Another great facility is with some difference of potentiality and rapidity derived from the extreme simplicity of regulation of action of the lamp, which is illustrated on page 411 of vol. xxxiii., and involves no extra apparatus whatever. All the lamps are of the same pattern, the difference between the large and the small ones consisting in the winding of the magnet, the diameter of the carbons, and the length and diameter of the arc. As the intensity of the current existing in the arc for each lamp depends upon its resistance, it is necessary that each should be carefully adjusted, and accordingly Mr. Gulcher has fitted up a very complete testing room in the works, in which every lamp is submitted to several hours' continuous trial, while at the same time the current passing through it, the difference of potential at the terminals, and the form of the arc are carefully noted. Although all the lamps are identical in principle, and in relative main characteristics, yet there is considerable variation in their external form. In addition to the table lamp shown in the illustration referred to above, the company manufactures a hanging lamp, a bracket lamp, and a sleep lamp, in which the arc is hidden in an inverted open-mouthed cone of opal glass, and the light is

(thrown on a white reflector above, and so distributed. The incandescence lamp of Professor Crookes is at present but little known to the public, but the great reputation of its author cannot fail to procure for it a favourable reception. Its manufacture is carried on, in a separate part of the works, where special apparatus has been erected, and every arrangement been made for producing the lamps in large quantities and at a cheap rate. Glass-blowing machines have been introduced, and an improved form of Sprengel pump, by which as labour is utilised as far as possible. The filaments are made from threads wound upon spun fragments of boxwood in cupro-ammonium until the cylinder attains the desired size; they are then withdrawn from the ammoniacal solution and carbonised to a black colour from the presence or contact to reddish, this they are soaked in weak acid, after which they are ready for carbonisation. This is effected in the usual way, the filaments are then inserted in the globes, and their resistance regulated by the passage of a current through them, while in an atmosphere of chloride of carbon. There is a large Crookes' installation, including 600 Crookes' lamps, at the Crystal Palace Exhibition.

Engineering, March 2, 1882.

ELECTRIC LIGHTING NOTES.

THE works of Messrs. Martin, Sons, and Co., of Lindley, near Huddersfield, have been lighted by the electric light by Mr. Wilson Hartnell, of Leeds. The installation includes three Crompton-Rimgin dynamo machines, nine Crompton-Crosley arc lamps, and twenty-nine Swan lamps. Eight of the arc lamps are fed with a current of fourteen ampères each, and one placed in the dye-house for matching colours, with twenty-eight ampères. The entire installation is very successful.

The Electric Lighting Committee of the Leeds Corporation have unanimously accepted the tender of Messrs. Paterson and Cooper, of the St. Paul's Telegraph Works, London, for the lighting by electricity of the library portion of the new municipal buildings which are to be opened in Easter week. The contractors undertake to carry out the work for 1500*l.* The dynamo machines will be driven by two of Messrs. Crossley Brothers' twelve horse-power Otto gas engines which, however, as the engines have already been purchased by the Committee, and the work in connexion with the electric lights is to be completed within two months from the acceptance of the tender.

It has been decided that the Jablochkoff Electric Light and Power Company shall be wound up voluntarily with a view to reconstruction, under the supervision of the Court. This will be a matter of surprise to many, who knowing that the company started with a good system, and has not spent much in perfecting it by experience or in advertising itself, imagined that it might at least not lost much of its capital, even if it has not made any profits. The extension of the Jablochkoff system on the Continent, coupled with its extreme simplicity, appeared to promise for it a more successful career there than its promoters have succeeded in securing for it, and it is difficult to comprehend why it is that its operations have been so limited. The company was established in the latter part of 1882, with a capital of 300,000*l.* in 60,000 shares of 5*l.* each. The electric light fever was then at its height, and 240,000 shares only were subscribed for by the public, representing, however, a cash capital of 1,200,000*l.* Twenty thousand fully paid up shares were issued as the price of the patents, and the same number remained unissued. The directors agreed to be sent that the chief feature of novelty consist in give 60,000*l.* in cash to the promoters. The wisdom of the absence of a reflector and the use of a holophote, this course is extremely questionable, and the policy of giving such enormous sums for patents, however valuable, when the vendors are willing to sell for scrip, is always questionable, and in this case the balance sheet submitted to the meeting showed other facts which cast still more serious doubts upon the good policy of the management. It is a pity that a company which has an established reputation, a system which has many excellent features, a capital which, though not large, is sufficient, and whose assets exceed its liabilities, should have to resort to winding-up for the purpose of reconstruction, although the process is no doubt a convenient one in some respects. We have always had a high opinion of the Jablochkoff system, and trust that it may soon again be in the front under more favourable conditions.

On the evening of last Friday a party of gentlemen from the Admiralty, the War Office, and several foreign governments, met at the works of Mr. Peter Brotherhood in Lambeth to witness the trial of a new search light, constructed by Messrs. Siemens Brothers for Mr. Gordon Bennett's yacht Namouna. The beam was projected across the Thames on to the clock tower of the Houses of Parliament, and elicited the unanimous admiration of the spectators by the extraordinary penetration of its powerful rays. The optical arrangement is a long focus holophote of the third order, consisting of a central lens and four concentric rings, the whole being about 22in. in diameter. In the front of this there is mounted, in a hinged frame, a sheet of plate glass to protect the lenses, which become warm from the heat of the arc, from splashes of sea water and spray. The lamp is fed by a current of 100 ampères, and is regulated by hand. The upper carbon is set behind the lower one, so that the crater is turned towards the lenses, and nearly all the light directed towards them, and to still further increase this effect the lamp is inclined at such an angle that the glowing surface of the carbon is approximately vertical, and parallel to the general plane of the holophote. When alternate currents are employed, and the carbons consequently consume symmetrically, the lamp is placed, of course, in the usual position. The motions of the carbons are regulated by a handwheel by which either or both of them can be moved, while their appearance can be observed through several coloured glass windows in the casing. To insure that the luminous centre shall be maintained in the optical focus of the instrument an image of the carbons is projected on to a screen by means of a lens and a mirror, and thus it can be seen at a glance if the consumption of either carbon is greater than that for which the gearing is arranged. The whole apparatus is mounted upon trunnions carried in two arms united to a vertical axis capable of rotation, and thus the light can be turned in any direction whatever. The arms are hollow, and serve as passages for the leading wires from the lamp; these are connected to permanent sliding contacts on the central axis, moving over corresponding contacts on the base. There is a graduated circle upon the base, and a semicircular quadrant upon the casing containing the lamp, and by their aid the light can be directed on any spot whose position has been found during the daytime by means of a theodolite or similar instrument. This arrangement is more particularly intended for service on land. Special care have been taken to prevent the objectionable heating which has characterised nearly all search light apparatus hitherto made. The casing is made of ample size, and has double sides, ground and between which a vigorous ventilation is maintained by air inlets and outlets, below and above. Over the mirror is erected an escape pipe, protected by a hood, for the air and the heated gases which rise directly into it, and no efficient is the arrangement that no part of the exterior of the apparatus becomes more than pleasantly warm to the hand. There is also an apparatus for transmitting signals by the Morse code, which has the advantage of allowing signals to be sent with the whole beam of light, either concentrated or dispersed by means of an additional lens—a result which has not been hitherto obtained. There is ample ventilation of the lantern. The current is produced by a Siemens dynamo of the type D, connected direct to a Brotherhood three-cylinder engine by an elastic coupling, and running at 400 revolutions per minute. Thus it will of novelty consist in the absence of a reflector and the use of a holophote, by this means a very narrow and concentrated beam is produced, while the long focal length of the lenses permits of the arc being kept at a safe distance from them. This latter is a most important point, as hitherto the glasses have often suffered from the heat and flame emitted by the arc, and to the general arrangement, there is little to be said, except that it displays that minute attention to details and points of practical importance which more often than not make the difference between success and failure than do those which create greater scientific interest. The bridge of a steamship is a very different place from a laboratory, or even from an engineer's shop, a fact which electricians have often forgotten in the past.

is about fourteen miles long, and connects the Neath and Brecon, near Danyrarth, with the line of the North Western Railway at Llangammarch, thus forming a slightly more direct route than any existing between the North and Swansea and Neath. By the same Committee has been decided the contest for the traffic between Merthyr and Quaker's Yard, which was the object of the Bills promoted by the Great Western, the Rhymney, and the Taff Vale Railway Companies; early in the day the first-named company retired in favour of the second, full powers over it having been secured, and now the Committee have granted the line of the Rhymney Company, with full powers, &c., over to the Taff Vale Company, thus fulfilling our surmise of last week.

Sir Robert Lindsay's Committee has also passed the preambles of the Bill of the Great Western Railway Company, by which they seek to connect the Rhondda Valley at its southern end with Cardiff by means of their Ely Valley line in one direction, and with Swansea by means of their Llynvi and Ogmore line in the other. This connecting line is about four miles long, and is a nearly direct line from the Porth station of the Taff Vale Railway to Herdon Forchan junction on the Ely Valley line.

Mr. Paget's Committee have evidently had similar views with regard to the Alnwick and Cove. bill; Bill of the North-Eastern, and that of the Central Northumberland Railway, for they have passed the former in its entirety, and the southern portion of the latter from Newcastle to Scott's Gap, and at the same time suggested the expediency of the construction by the North-Eastern Company of the line between Rothbury and Woolperton, the rejected link of the rival scheme; if the evidence of their witnesses is to be relied on it is obvious that the North-Eastern Company have without doubt by far the best of the fight, as they have obtained their desire, and at the same time broken up an opposition line of communication.

The Kilsyth and Falkirk Railway Bill has been passed by Mr. Paget's Committee, and they are now occupied with rival schemes of the Great North

4. That, as to the comparative liability of an ironclad and an unarmoured ship to be sunk by projectiles, there is much less difference than is generally supposed.

5. That for the coast of any invaded we could have three armoured ships of far higher speed and carrying calibre than would be carried by any ship which the enemy could have available for such service; the combat between three armoured cruisers and one ironclad, considered to be fairly matched, because representing the same pecuniary value; and assumes the victory would lay with the three armoured ships; and, without entering into the technical questions concerning "dust fighting" concludes that the result would be the same if the number engaged on each side were proportionately multiplied.

6. That, as to the provision for more enormous Navies than we possess, or are ever likely to possess, unless we really declare our expenditure on individual ships; and to do this we must dispense with armour, and that the sites' expenditure of the country should be upon fast unarmoured ships, with enormous gun power.

7. He condemns the use of coolers impressed out of merchant steamers, and further points out the importance of the public not being alarmed by the exaggerated accounts of damage we have at all times seen in our ships, and that, in addition to their loss, we have also a grand against the interception of food supplies, and that as our population increases and our agriculture declines, the more terribly effective for reducing us to submission would be the stoppage of these supplies.

I agree entirely in this last suggestion. I have never considered a reliance on our agriculture for our supplies as at all sensible, and the southern portion

and while presenting a much more elegant appearance, they are not so liable to crack under the influence of unequal heating, and there is a smaller loss of light through refraction and internal reflection.

A considerable portion of the work of manufacturing the lamps is, we understand, performed by machinery, by which greater uniformity is insured; but the chain of operations by which the rough materials are converted into a finished incandescence lamp, is identical in its sequence and character with that of hand-made lamps, and will be understood from Fig. 3. The bulbs or flasks are delivered from the glass works in the form shown at No. 1. The first process is to heat the closed end and draw out a hollow cone, shown in No. 2. To this little cone is then fused a short fine tube, by which the envelope is afterwards to be exhausted and attached to the exhausting apparatus. The bulb then presents the appearance shown at 4. The next process is to prepare the glass stem, by which the lamp is hermetically sealed and within which the platinum conductors are fixed that are to join it to the connecting fitting. A piece of tube, No. 5, is taken, and its two ends are drawn or tapered off, as shown in No. 6. It is then thickened up in two places (see No. 7), between which it is divided into two separate tubes, shown at 8 and 9, two platinum conducting wires are then passed through the tube (see No. 10), care being taken that they do not touch one another. The large end is then heated nearly to its point of fusion, and is then squeezed flat so as to cause the platinum wires to be closely imbedded within its substance. The little crushed piece, shown in No. 11, are then soldered to the ends of the wires, and to these are attached, by an electric deposit of pure copper, the ends of the carbon loop to be presently described. The glass stem with the carbon filament attached, is then introduced into the neck of the bulb, to the point of which its thickened portion is attached by fusion, so as to form with it one piece of glass. The three down and is then trimmed off square, as shown in No. 13, which also illustrates the drawing down of the pieces of the exhausting tube, so as to form two capillary constrictions. This tube having been attached by a mercury joint to a Sprengel pump, the bulb is exhausted, and when the required exhaustion is complete, the contraction nearest the pump is sealed off, leaving a short length of tube attached to the bulb by a capillary neck, but exhausted to the same degree of internal residual pressure. A second sealing off at this neck renders the hermetical closing of the lamp complete, the object of the double sealing being to guard against any leaking at the two ends (see No. 13), so that two filaments may be constructed out of the same bamboo strip. The threads so far prepared are then laid in moulds consisting of nickel plates in which grooves are cut of the forms shown at 11, 15, 15, 16, or 17; a flat nickel plate is then fixed over them, so as to enclose them and prevent the admission of air during the process of carbonisation, which is effected in raising the moulds with their contents to a high temperature by placing them in a muffle and heating them to incandescence. When the moulds are opened the filaments are in a condition to be electro-plated to their platinum supports and introduced into the lamp-bulbs, but yet another process is required to confer upon them their perfectly homogeneous and elastic character, as well as their refractory nature at high degrees of incandescence, which are necessary characteristics in an incandescence lamp. This further process is applied when the lamp is attached to the pump and while exhaustion is going on, and consists in alternately heating and cooling the filament in the Sprengel vacuum by passing currents of electricity through it of increasing strength until high degrees of incandescence are reached and between each increase of current allowing it to cool down, exhaustion going on all the time. By this process, which we have fully described two years and a half ago in an article upon "The Physical Alteration of Metals,"* not only are the occluded gases eliminated, but as the fibre is subjected to a far more severe test than it can ever be subjected to in working, none but the "fittest" survive, and a healthy generation of lamps is insured.

We now come to refer to the different methods adopted by Mr. Edison for mounting the lamps and applying them to commercial or to domestic use, and those of our readers who desire to see the many

* See ENGINEERING, vol. xxxiii., page 337.

surfaced to one another, so as partly to project throughout the whole of its length; this projecting portion is then cut away with the exception of a little piece at each end, so as to leave a fine thread of bamboo fibre having enlarged portions at either end as shown in the figure at No. 16, or if the intended filaments are for the half-lamps an enlarged portion is left in the middle as well as at the two ends (see No. 15), so that two filaments may be constructed out of the same bamboo strip. The threads so far prepared are then laid in moulds

ELECTRIC LIGHTING NOTES.

The ordinary general meeting of the Anglo-American Brush Electric Light Corporation, Limited, was held on the 21st inst. last under the presidency of Sir H. W. Peek, M.P. The chairman referred to the accounts which had been briefly alluded to in the circulars forwarded in reply to them one by one. Beginning with the second item, he did not think explanations would be necessary, for salaries, of which £5,392 was paid, was not a large amount. The latter, he admitted, was a large amount, but it was only what was authorised by the articles of association to be given them as a proportion of the dividends of 100 per cent. lately paid to the shareholders. The miscellaneous charges of the workings into sudden darkness, or possibly in a fiery mine cause an explosions by a spark or stuff not being formed between two exposed portions of the conducting cables.

It is to be noted that Mr. Edison's representatives do not put forward his applications illustrated in Figs. 11, 12, and 13, as any part of the system, but solely as illustrations of applications to which it may lend itself, as well as to meet certain requirements which are constantly being asked for.

Having in this and the preceding notices described the lamps employed in the Edison system, as well as the dynamo-electric generators, by which the currents or apparatus bought by the sub-companies, we shall in our next article refer to the conducting cables and connections, as well as to some of the switches and other accessory apparatus employed in the Edison system.

Engineering, Jan. 25th 1884.

The International Electric Company held its general meeting on December 31. The report stated that contracts had been entered into for the supply of 13,501*l*., and that the revenue from the gross value of was 2641*l*., with an early prospect of an increase to 11,209*l*. The company has arranged with the whole of the Imperial Theatre House in Vienna, the streets of Temesvar, in Hungary, and to supply certain fittings for installation of light works in the palace of the King of Roumania. The street lighting is to be effected by Lane-Fox lamps and Brush dynamo machines, the lamps being arranged in multiple series and the series being carried overhead. The company has issued 26,685 shares, on which 3*l*. each has been paid, and has allotted 12,500 shares as partly or fully paid. They owe 3543*l*., and have 12,985*l*. in hand, 1256*l*. lodged as caution money, and 1774*l*. due to them. Their patents have cost 27,000*l*. in cash, and 48,000*l*. in shares, and their stock is valued (included erection) at 34,320*l*. The general expenditure during the previous eighteen months amounts to 20,616*l*., of which the principal items are brokerage 1,000*l*., issue of shares, 981*l*.; directors' fees, 2000*l*.; salaries, 8000*l*.; rent and taxes, 1075*l*.; travelling expenses, 1696*l*.; wages (exclusive of contract), 1001*l*.

NOTICE.

The Proprietors of "Engineering" beg to state that Mr. H. G. Reeve Thompson, who until recently acted as an Advertising Canvasser for this journal, no longer their authority to solicit new advertisements on their behalf, but that Mr. Howard Ellis is their sole authorised agent for the provinces.

The Proprietors also beg to state that they have entirely withdrawn their support from the French periodical known as "L'Ingénieur," with which they have now no connexion whatever.

ENGINEERING.

FRIDAY, JANUARY 28, 1883.

ELECTRIC LIGHTING IN MILLS.

The cost of electric lighting will be lessened, we are told, when it is undertaken on a commercial scale. This no doubt is true, for the installations hitherto erected have partaken to a large extent of an experimental character, and have necessitated expenses of supervision and management that have been out of all proportion to the light produced. But there exists at present one field for electric lighting in which it would possess very positive advantages that can be conceived as pertaining to the largest development that may be expected, and this is the lighting of mills. In the case of a factory the expenses of the electric light can be reduced to the lowest possible point, for the generator would presumably be driven by an engine that had been most carefully designed to insure economy, and the only working expense that need be charged against the installation would be fuel. No millowner in reckoning up his gas account includes a share of rent for the standing room of the meter, or for the space occupied by the pipes, and millowner would look for a dynamo machine, which is certainly not larger than a gas meter of equivalent lighting power. Again, while incandescence lighting the amount of supervision required, once the apparatus is properly erected, is almost imperceptible, certainly nothing more than the engineer could easily bestow in the intervals when his attention was not required by his engine. Such being the case the cost of electric lighting under the circumstances we are assuming, would be made up of four items only, namely, interest, depreciation, fuel, and renewals.

Having thus settled the character of the charges we will now consider their amount, and for this purpose will assume an installation of 200 16-c.p. lights, suitable for a mill or manufactory of a fair average size. The first cost of the plant complete and ready for work would be, at present manufacturers' prices, 9000*l*., and upon this there would be an annual charge of

	£	s.	d.
Interest at 5 per cent. per annum ...	450	0	0
Depreciation at 5 per cent. ...	450	0	0
Repairs to machines and belts ...	7	10	0
	907	10	0

Now the cost of a meter and gas pipes for 200 lights would be 120*l*., upon which interest and depreciation amount to 12*l*. per annum.

Seeing that the cost of electric lighting is made up as largely of fixed expenses, while that of gas lighting consists mainly of current expenses, it is evident that the latter must have the advantage when the periods of lighting are short. According to the Factory Act, women and children must only be employed between the hours of 6 A.M. and 6.30 P.M., or between 6.30 A.M. and 6 P.M., consequently in a mill employing women to any great extent, the period during which light is required is only about 300 hours per annum. For this period the expenses would be

	£	s.	d.
Fixed expenses (as above) ...	907	10	0
Renewals—200 lamps—each lasting 2000 hours at 5s. each = 500 = 25 ...	12	10	
Coal—6000 horse-power hours at 3½*d.* (per horse-power hour—at 6 lbs. a ton ...	3	12	
	86	7	

Cost per lamp per annum 8*s.* 7*d.*

The cost of gas for the period during the same time would be:

	£	s.	d.
200 burners, at 5 ft. each, with gas at 3*s.* 6*d.* per thousand	375	0	
Fixed expenses	15	0	
	60	0	

Cost per burner per annum 6*s.*

It thus appears that, under the most favourable conditions, a mill running fifty-six hours a week cannot be lighted by incandescence lights for the same cost as gas. But there are many exceptions to the fifty-six hours' rule, such for example as in lace mills and bleach works, which run night and day, using artificial light 6000 hours per annum. In these conditions the total annual cost for the electric light would be 231*l.*, or 1.16*l.* per light per annum. For the same time the cost of gas lighting would be 600*l.*, or 2.25*l.* per light per annum, that is, rather more than double that of electricity.

Putting the matter another way, the cost of an incandescence light per hour under the assumed conditions, varies from 0.34*d.* to 0.026*d.*, and of a gaslight from 0.24*d.* to 0.18*d.* By a simple calculation it will be found that the two systems equate at an annual working period of 670 hours, when the expense per hour and per lamp, both for gas and electricity, is 0.212*d.*, from which it follows, if our figures be correct, and we do not think that they are too favourable, that under no circumstances likely to be met with in practice can an electric incandescence lamp, burning less than 670 hours per year, be maintained under the price of gas, when the latter sells for 3*s.* per thousand feet.

The charges of such an electric light installation in this country can only be arrived at by calculation, but there are in America already sufficient actual data in existence to show what can be accomplished in practice. In a recent meeting of the New England Cotton Manufacturers' Association a paper was read by Mr. C. J. H. Woodbury on "Electric Lighting in Mills." From this it appears that up to last May there were seven of the establishments under the control of the Mutual Mill Insurance Companies provided with electric light, which, in some cases, had been at work sufficiently long for a fair comparative estimate to be made between it and gas in the matter of expense. The price of gas in America is always high, and varies considerably at different places. The majority of mills are lighted with gas made by the destructive distillation of petroleum. At it of 80-candle power, but is generally reduced to 40-candle power by mixing air with it, and is burned through "sun burners" (luminal) burners, which consume one and a quarter feet per hour. The annual cost of coal gas per burner is 7*l.* 10*s.* to one dollar. One large corporation, with exceptional privileges, makes its coal gas at an annual cost of 60 cents a burner. Another corporation inland makes its coal gas at 1.25 dols. per thousand feet, or at an annual cost of 1.75 dols. per burner, each burner consuming 1432 cubic feet (or two large mills in the same city, sun discharging similar goods, the more modern one makes its gas at an annual cost of 70 cents per burner, while the older one buys coal gas at 2.65 dols. per thousand feet. In all the instances intend upon about 6 per cent. forms an item in cost. A mill running 60 hours a week, using goods and running 60 hours a week, generally uses 2,000 to 3,000 burners, a mill that runs 110 hours a week requires light for 4000 to 4500 burners a year. A mill making goods used a large number of lights, and uses them an additional hundred hours a year.

The cost of new lights in several steam mills running 400 hours per year, is 6*l.* 5*s.* per burner, of which 1*l.* 10*s.* is for cashiers, and 5 cents for attendance, and 4 cents for engineering. When such runs all night the hourly cost is diminished. The number of new lights that must be lighted to light the loom on 700 to 1400 square feet of floor, ten and one-half feet in 1000 to 2000 square feet. A cash room 8ft. × 100ft., containing 64 cards, has been lighted by 6 gas jets or lamps. As a basis of comparison for cost, there is subtract the case of a weaving room where twenty-four gas lights replaced 252 6-ft. burners, consuming together 1752 ft. of gas per hour. These gas light therefore entailed the consumption of 73 ft. of gas per hour. A careful estimate shows that each new lamp cost 64 cents per hour, which corresponds to gas at 89 (58.9*d.*) cents per thousand. A similar estimate in another mill gives the cost of lighting by gas at 2188 dols., and by electricity at 1125 dols., the latter amount corresponding to gas at 90 cents (3*s.* 9*d.*) per thousand. In both these establishments the lights were used about 450 hours per year.

One of the Merrick Thread Mills has been fitted with Edison incandescence lights. This mill runs all night in the busy part work for fifty-one weeks in the year, using artificial light 2820 hours per annum. It was formerly filled with 70 burners, using city gas costing each 2.13 dols. per month (25.56 dols. per annum), or 2*l.* 2*s.* 6*d.* in all. These lights were replaced by 95 Edison B (eight candle-power) lamps. The cost of 2,000 hours five hour lamps had broken, and when the installation had been running 1278 hours eleven had broken. Allowing the lamps an average life equal to six months' use, the cost of lighting is made up as follows:

	dols.
190 lamps at 1 dol.	190.0
Interest and depreciation	153.50
Six horse-power at 10 dols.	60.00
Annual cost Edison light	403.50
Monthly	33.62
Monthly gas cost	797.00

This gives the annual cost per light of eight

Electrical Review
Feb. 12, 1883.

THE ELECTRIC LIGHT IN PARIS.—Some very successful experiments on the electric lighting of the *foyer* of the Opera House by the aid of Faure accumulators and Swan lamps took place last week at Paris. It is the idea to light the whole house by means of from 600 to 700 lamps of this system. The lamps were first shown to the public on Friday, September 29th. They have been placed in several parts of the building, but most prominently in the *foyer*, the extremely elaborate decorations of which have been entirely spoiled by the ruthless effects of gas. To light the *foyer* with gas 10 chandeliers, with 48 lights on each, were used, equivalent to about 4,800 candle-power. Two of these chandeliers have been fitted with 48 Swan lamps each; these were run up to about 40 candle-power, making a total of 3,840 candles for the two chandeliers, almost exactly equal to the eight chandeliers with gas. The effect upon the neighbourhood of the electric light was exceedingly marked, and the representatives of the Opera House, who witnessed the trial, expressed themselves extremely pleased with the result. We may add all the main cables were covered with lead, and every lamp was protected with lead or cut-outs, to avoid any possible chance of fire. The electric illumination of the shop of M. Sandoz, the well-known jeweller of the Palais Royal, has been discontinued, and doubtless will not be taken up again, at least under the same circumstances. This illumination was made with the aid of accumulators charged at the works and carried, insulated, to the lamps. These unfavourable and uneconomical conditions are, we think, the cause of the discontinuation of this lighting. The Grand Café and the Théâtre des Variétés, continue their electrical illumination with the same success.

ADVERTISER, NOVEMBER 6, 1882.

ELECTRIC LIGHTING.

That electricity can be practically applied on a commercial basis for the production of light is a statement which will probably not be disputed in the face of the hundreds of electric lamps, both "arc" and "incandescent," that at present illuminate the streets of most of our large towns. The large sums recently subscribed towards the floating of Electric Light Companies indicates how thoroughly public interest has been aroused in this newly-discovered adaptation of an hitherto uncontrollable element. It also in many instances indicates how little is known by the investing public of the laws which govern its production and management. The question, therefore, whether any of the systems now in use deserve to be regarded as superior to the old methods of artificial illumination is one which fairly becomes of more and more importance. It is perhaps unnecessary to explain the difference between "arc" and "incandescent" lamps, but for the benefit of those who may not know it is sufficient to say that the "arc" light is produced by the momentary contact and withdrawal of the carbon pencils or "electrodes" during the passage of an electric current of high intensity. That given out by the "incandescent" lamp is caused by the passage of a current of low tension through an infusible conducting filament placed in a glass bulb from which the air has been exhausted under high pressure. Whatever advantages the arc lamp may possess for the lighting of large spaces, and they are many and obvious, Edison claims that it is clear that this kind of lighting is totally unsuitable for purely domestic purposes. We are all familiar with the cold, blue, flickering light, and the sputtering glass globes which soften in some degree their blinding rays—a concentrated but cold light, casting shadows of the most intensity wherever the smallest projection occurs, giving a cavernous appearance to the eyes, and neglecting the shadow of the nose down on to the chins of those who pass near them. This extra brilliance concentrated in one spot is not quite the kind of light that accords with our ideas of perfect lighting. Moreover, the necessity of screening or lessening the power of the light is unquestionably unnecessary. There is also another and more serious objection to this mode of lighting—the many, and in some cases fatal, accidents which have occurred from inadvertent or accidental contact with the wires conveying the current. The danger which is always more or less present, owing to the great intensity of the current required for this class of light, but which does not exist in the conductors of incandescent lamps. It is therefore to one of the many systems of incandescent lighting that we must look to find a lighting agent that must exist in houses—namely, safety, economy, individual control, and economy. With the highest appreciation of the efforts of our own countrymen in this direction, yet the wonderful strides made in America so far exceeds anything yet undertaken in this country, that it is there we at once turn to find a solution to the question. The lighting up of a large area in New York, at present comprising some hundred or so of dwelling-houses, and most practical test to which electric lighting has yet been put, and it is interesting to know what are the main features of a system which has secured the support of a large section of a city whose inhabitants are not likely to give such support from any merely sentimental admiration for an inventor, Edison, great though their admiration doubtless is. The "plant" was started and the district lighted up for the first time on September 4th, since when the station has been running night and day without stopping, and so far no serious obstacle has been met with. The

[illegible] is generated by six dynamos, each carrying twelve hundred lamps. The distributing mains, which are laid in the ground and tapped for branches in much the same manner as gas mains, consist of rods of copper encased in iron tubes. Of these there are at present over 29,000 feet laid in the district, and although they have been underground on an average nine months and have been in constant use since September, the leakage on the entire network only amounts to about 85 milliontths of 1 per cent., or about 00427 of one horse-power per minute. From the street mains the branch supplies are taken to the houses. Each house is furnished with a meter, by which the amount of electric current consumed by the occupier is measured. The meter is constructed on the principle of electrometallurgy. The current passes through a solution of sulphate of zinc having zinc "electrodes," and in its passage decomposes the zinc of the one plate and deposits it on the other, and as the result of electricity deposits an equivalent of zinc, by simply weighing the plates the exact amount of current can be ascertained.

The wires inside the houses are either quite concealed behind the plastering or carried under small wooden casings, or in the inferior parts are simply carried along the face of the walls and secured with clients. But in no case is there the smallest danger to life or property, the low electric pressure or tension of the current is such that only the smallest possible shock can be felt even on handling the naked wires, which, under all circumstances, are covered with a perfect insulating material. Absolute immunity from danger by fire is secured by an ingenious device of the inventor of the system, which consists in inserting at every branch and in every main a small block containing a piece of thin lead wire which fuses at a very low temperature, and at once stops the flow of the current. This prevents any dangerous heating of the wires, and extinguishes only the lamp or lamps on its own circuit, without in any way affecting the others, and also possesses the advantage of being repaired by simply screwing in another of the small wooden plugs, which may be done in a few seconds by the most inexperienced. The lamps are of the well-known, open-chambered pattern, and give a soft steady light, controllable in the same way as an ordinary gas-light by means of a small tap, but possessing advantages over the gas-light which may only be experienced to be appreciated. No danger of explosion here through taps turned off sufficiently to extinguish the light, and then turned on first one and then the other tap is turned on or off, so it burns or is extinguished, and there at once is the light, without the aid of matches or lighted paper, and often as it

The Sun, Saturday, Dec. 9, 1882.

ENTERTAINMENT ON BOARD THE STEAMSHIP TARAWERA.

The Union company assembled on Prince's Pier, Princes Dock, Liverpool, to witness the embarkation aboard the s.s. Tarawera of friends bound for the antipodes, and a number of others similarly engaged. The passengers on board, both cabin and steerage, were likewise cheerful-hearted greetings, crowned the occasion with a most pleasant entertainment. The weather was stormy, but the weather improved as the day advanced, and the passengers were enabled to leave the vessel with ease. Here they found that comfort had been made for their comfort by the officers and crew of the Tarawera, a handsome vessel of 2,000 tons burden, recently launched from the yard of Messrs. William Denny and Brothers, Dumbarton, for the Union Steamship Company of New Zealand, Limited. She is built of steel, and is manned by a fine British crew of the highest class. The vessel is fitted with the electric lights throughout, and is admirably suited to meet the requirements of the trade. When the passengers had taken their places at the tables the Rev. Dr. Macnaughtan, who had been appointed by the builders to preside over the proceedings, in the absence of Mr. Charles Grant, the enthusiastic mathete who has been the means, in the vessel to fit up one of the specially designed and painted panels, for the social entertainment usually under the poop in most merchantable appartment. At one end is placed a piano by Messrs. Collard, which was accompanied by a fine American organ by Messrs. Warren. A compact library, by Messrs. Smith and Co., Glasgow, will be available for the voyagers who may like to while away the time with pleasure and profit. The main saloon is a very handsome apartment, lighted from the roof by handsome stained-glass windows, on which are represented the national flowers. The panelled with mirrors and contained ornamental wood, on which classic designs have been carved. Between the panels are pillars of white enamelled wood, the effect of the whole being most pleasing. The floor is covered by one of the finest specimens of linoleum American walnut, covered with Utrecht velvet pile carpets, while the apartment is so lofty and well ventilated as possible to thoroughly ventilate the apartments in the tropics, will add greatly to the comfort of those who have the misfortune of the description. The ladies' state-room, which is the portion of the saloon reserved for the exclusive use of the passengers of that sex, has been tastefully furnished, there being in each a lavatory constructed on the most approved sanitary principles. The cabins are fitted up with Archibald Stewart & Co.'s spring mattresses, and are placed a la-de-la, disinfectants for its use in case of sickness. The cabins are so arranged that each alternate one was used as the apartment. At the stern there is a commodious smoke-room, tastefully painted in shades of blue, the seats being covered with bubble leather, and on the walls being hung handsome trophies of arms. The bath-rooms and lavatories are handsomely decorated in ranges royale, with pillars of white marble, and the floors are laid with hard wood, in imitation of tabinet, the ceiling being painted white and relieved by gilding. Throughout those apartments there is no lack of evidence of reasonable bills. A portion of the saloon has been set apart as a children's room, where their creatures's wants will be duly attended to, and for their amusement a miniature saloon has been fitted up. The apartment is so constructed that ship's officers are placed midships on the main deck, and the accommodation for the crew and firemen is placed forward. The second cabin is also a spacious cabin, and there is also a separate cabin for the use of lady passengers, which has been fitted up by the Edison Electric Light Company, Limited, Queen Victoria-street, E.C., lighting. On the Glasgow, and the company's large number of scientific gentlemen, among whom were Professor Sir William Thomson, Mr. William Henry, and others inspected the vessel on Thursday, Saturday. On that day the lights at Greenock on the arrival of Mr. Grant, who was pulled at a the direct brilliancy, but on the following day another was added at 500 a beautiful light was produced. The electricity the company has been to their efforts in this direction have been successful, the light afforded by the Edison on board resulting with the highest praise. From the company and several scientific gentlemen [illegible] [illegible]

[illegible] board. The entire work account of the machinery required to construct the light is [illegible] and Hart Street. The electric station was under the charge of Mr. Bradbury, of Westminster, & Co. Among the company on board were Messrs. Peter and John Denny, Mr. William Brock, Captain Hamilton, R.N., Mr. Hall, Superintendent of the Union Company of New Zealand, Mr. M'Allister, inspecting engineer, Mr. Charles Grant, Mr. Mitchell, Glasgow, Mr. Hall, Greenock. The vessel was to have been despatched on Thursday afternoon, but was detained owing to the non-arrival of several passengers from Scotland, who were unable to reach Greenock in consequence of the thick fog on the railways. On their arrival yesterday they were taken on board, under the skilful guidance of Captain Hamilton, and an efficient crew. The following is a list of the passengers:—

First Cabin.—Ardrille—Mr. and Mrs. G. Barry, Miss and Master Barry, Mr. and Master Ida, Mr. Bruce, Mr. Mrs. Bruce, Melbourne; Mr. and Mrs. C. L. M. Lindsay, Miss Lindsay

The Republican, Garland, Dec 13. 1887.

LIGHTING A BREWERY.

Edison Electric Light Company's Dynamos Running with Electric Lamps—The Danger of Wires on Poles.

An opinion has been expressed that the day is not far distant when the different buildings of this city will, on the darkest nights, be illuminated to a brilliancy that will compare favorably with the light of midday. On Saturday one section of the Edison light installation was started in the buildings of the Phillip Best Brewing Company, and, in about two weeks, 700 Edison globes will be in operation. In malthouse, No. 1, there are 220 incandescent lights, and in the cellar and other buildings and Frederick Pabst's residence, there are to be 480 additional lights, 700 lamps, and 11 lamps of ten to twenty candle power. The dynamos and engine are located on the corner of Chestnut and Tenth streets, in the boiler and engine-room. The engine is one of Edison's latest vertical, runs at a speed of 350 revolutions a minute, and develops seventy-horse power. The cylinder of the engine is 8x9 inches. The dynamo machine is sufficient to furnish currents through the entire system. The revolutions of the armature are 1,200 per minute, and the total electro motive force of the machine is equivalent to 110 Volts. The underground conductors, of which 300 feet have been laid, were tested in the factory at New York at 100,000,000 Ohms, and, after being placed underground, were tested at 20,000 Ohms to and fro current. His most severe test that they could be subjected to. In the test, the loss of electricity was nothing. The current used in the underground tubes conveys the electricity from the machine to the different buildings and the total resistance, when all the lamps are in operation will not exceed 1 in those conductor tubes. Each light and each group of lights is controlled by safety cutouts, forming an electrical guard against fire or an overcharges of electricity.

Henry E. Meade, general agent for Wisconsin of the Edison Electric Light Company, when asked to explain the system, said: "Our system is about the largest station of 14,331 lights, distributed from the Produce Exchange district, where a 75,000 feet of conductors laid underground. They have been underground, on an average, for about two years, and tests show that the loss of current in the entire network is forty-eight millionths of 1 per cent, and, were we to light the entire city of New York with, say 400,000 lamps, and, taking the Produce Exchange District as a test, the loss of current from leakage would not be sufficient to run a single lamp, or, to be more explicit, 400 tenth of one-horse power. Then, you see, the loss of current by our underground system is almost unappreciable. We have installed in the United States exclusive of the New York station, and have in operation, about 75,000 Edison lamps, of which 10 per cent. are underground.

"How do you register the consumption?"

"We meter our current by the deposit of metals and arrives at one one-hundredth of 1 per cent. of the amount consumed. We guarantee the average life of our lamp at 600 hours constant burning. The lamps are sold at the nominal price of $1 each.

"Do you think there is danger from wires on poles for are electric lights?"

"Where wires are run on poles there is great danger of their coming in contact with telephone or fire alarm wires. Should an electric light wire, having a powerful electric motive force, be caused by a telephone or fire alarm wire its result would be terrible, and nothing is more likely that might come in contact with it would ignite. The insurance companies are right in saying wires should be underground and the City Council should compel all companies operating them to do so, as above there. This is perfectly practical, and the only reason why are because it would take a little time and trouble to perfect a system of underground conductors. In fact, the wires would throw high tension currents, but should they come in contact with a man?"

"That mean would vary under different conditions. A person become connected with the ground by means of a wire with a high tension—say 2000 Volts and ten Watters current in circulation—he would meet with severe injury, if not death. Should a person become connected across the poles and receive the charge, I should not care to take his place, as I have had several mild shocks and they were sufficient to test the nerves of the strongest man in a grocer store. Although the human body is a conductor of several thousand Ohms, nevertheless the current finds its way through the veins and tissues of the body and causes paralysis. There have been at least twenty men killed by wires from this arc system, but we have yet to hear of the first accident from the incandescent system."

"Why is the incandescent system safe?"

"Simply because the Edison incandescent system uses but 110 Volts of pressure and about 1 and 75-100 Watters of current. To be fatal to life a current must be over 2500 Volts. Therefore, you will perceive that the difference in the safety of the two lights. I do not consider the system of electric light that will secure the safety of those who use it and of the buildings through which it runs. Therefore I say, if companies wish to do business let them put their wires where they will be safe and they cannot be safely placed over ground."

London Times, Dec. 2. 1882.

THE ELECTRIC LIGHT.

The total number of Provisional Orders for which applications relating to the electric light will be made on the next part the applications will be made by corporations and other local authorities. Only two metric—those of St. Pancras and Richmond (Surrey)—appear to be coming electricity in the areas within their jurisdiction. The principal applicant among the joint-stock companies is the Metropolitan (Brush) Electric Light and Power Company will be supplied for, to produce, supply, and store electricity for lighting and other purposes, to break up public and private streets, &c., and to erect, lay down, and maintain wires and other apparatus and works. Powers are asked to enter into agreements with the local authorities, to demand and recover rents and charges, to make applications as to Bills, &c. The districts for which these powers are sought are Islington, St. Pancras, City, Clerkenwell, and St. Luke; Battersea, Fitzwilliam, and Lupton; Hornsey, Highgate, and Southgate; Hampstead, Willesden, Hendon, and Finchley; Marylebone, Paddington, St. James's Westminster, and St. Anne, Soho; Kensington, St. Giles-in-the-Fields, St. George, Bloomsbury, and Holborn; Lambeth, Chelsea, St. Martin-in-the-Fields, and Westminster district; the Strand district, St. George, Hanover-square; Camberwell and Penge; West Ham, East Ham, and Wanstead; St. Olave, Bermondsey and Rotherhithe; Fulham, Hackney, Battersea-green, and Shoreditch; Chiswick, Acton, and Ealing; Islington, St. George the Martyr, and St. Saviour's, Southwark; Wandsworth and Wimbledon; and Greenwich and Lewisham. The Pilsen Electric Light Company (Limited) intend to apply for a Provisional Order for similar powers "in perpetuity or for such period as may be prescribed" to the City of London and the Districts thereof, St. Andrew, Holborn-above-Bars, St. George the Martyr, St. Sepulchre, Saffron-hill, Hatton-garden, Ely-rents, and Ely-place, and the Liberty of Glasshouse-yard: St. Anne, Soho; St. Paul, Covent-garden, St. John the Baptist, Savoy; St. Mary-le-Strand, St. Clement Danes, and the Liberty of the Rolls; St. Giles-in-the-Fields, St. James's, Westminster, St. Martin-in-the-Fields, and a portion specified of St. Margaret, Westminster; Clerkenwell, Lincoln's-inn, the Temple, Westminster Abbey, and the Victoria Embankment. The Swan United Electric Lighting Company (Limited) will apply for authority in four Provisional Orders "to produce, store, supply, and sell electricity, electric currents, and other like agency for public and private purposes" in certain portions of the Strand district, the Hanover-square district, the South Kensington district, and of the Brompton (London) district. The Pilsen-Joel and General Electric Light Company (Limited) intimate that they will ask for three Provisional Orders for certain streets in the Holborn and Strand districts, Marylebone, Paddington, and the City of London —Old Broad-street, part of New Broad-street, Liverpool-street, part of Throgmorton-street, Lombard-street, part of Gracechurch-street, Cornhill, and Leadenhall-street; Tottenham-court-road, &c. The Provisional Orders will be applied for as regards a specified portion of Chelsea and of the parish of St. John, Hampstead, by Syrencl, Thompson, and Ince (Limited). The Incandescent Electric Lighting Company (Limited) notify their intention to apply for a Provisional Order for powers to produce, supply, and sell electricity for Birmingham, Walsall, Smethwick, Smallfield, and Reading. The Union Electric Light and Power Company (Limited) will ask for eight Provisional Orders "to produce, supply, and store electricity for lighting and other purposes, to break up streets, to erect, lay down, and maintain wires, &c., and to enter into agreements with the local authorities" for Bermondsey, Greenhithe, Dartford, Wandsworth-cum-Earn, Malvern, Hyverstone, Aldershaw Burstall, Hartshill, Nuneaton, Atherstone, Polesworth, Dordon, Tamworth, Ashby-de-la-Zouch, Ashby, Packington, Coleorton, Whitwick, Earl Shilton, Barlestone, Stoke Golding, Dadlington, Sutton Cheney, and Shenton. Orders will be made by the south-eastern (Brush) Electric Light and Power Company, and by the Provincial (Brush) Electric Light and Power Company, the latter of whom will apply, in addition, for a Provisional Order to supply Sudbury. Authority will be asked for "to produce and supply electricity for lighting and other purposes, to break up streets, to erect, lay down, and maintain wires, &c., and to enter into agreements with the local authorities" for Cleobury-Mortimer, Ditton Priors, Neenton, Burwarton, Aston Eyre, Monkhopton, Upton Cressett, Much Wenlock, Bridgnorth, Quatt, Alveley, Claverley, Worfield, Ackleton, Albrighton, Donington, Tettenhall-Wood, Tettenhall, Codsall, Bilbrook, Pattingham, Patshull, Perton, Wrottesley, Featherstone, Shareshill, Brewood, Boscobel, Coven, Huntington, Cannock, Hednesford, Rugeley, Brereton, Armitage, Handsacre, Colwich, Longdon, Hamstall Ridware, Blithfield, Abbots Bromley, Admaston, Rugeley, Penkridge, Stretton, Acton Trussell, Bednall, Teddesley Hay, Cheslyn Hay, Great Wyrley, Churchbridge, Walsall Wood, Aldridge, Walsall, Pelsall, Brownhills, Norton-Canes, Shutford, Bodicote, Hardwick, Bloxham, Adderbury, Milton, Deddington, Hempton, Barford St. Michael, Barford St. John, Steeple Aston, Middle Aston, Somerton, Ardley, Fritwell, Souldern, Upper Heyford, Rousham, Lower Heyford, Steeple Barton, Duns Tew, Middle Barton, Chesterton, Wendlebury, Bucknell, Boarstall, Brill, Chilton, Dorton, Worminghall, Ickford, Shabbington, Oakley, Long Crendon, Chearsley, Waddesdon, Quainton, Grendon Underwood, Edgcott, Marsh Gibbon, Poundon, Fringford, Hethe, Stratton Audley, Bicester, Launton, Ambrosden, Arncott, Piddington, Blackthorn, Merton, Islip, Bletchingdon, Kidlington, Yarnton, Cassington, Begbroke, Hampton Poyle, Kirtlington, Shipton-on-Cherwell, Enslow, Wootton, Glympton, Kiddington, Sandford St. Martin, Heythrop, Chadlington, Spelsbury, Ascott-under-Wychwood, Shipton-under-Wychwood, Milton-under-Wychwood, Fifield, Idbury, Langford, Kelmscott, Filkins, Broughton Poggs, Holwell, Asthall, Swinbrook, Burford, Widford, Taynton, Upton, Great Tew, Little Tew, Enstone

THE ELECTRIC LIGHT FOR WAR PURPOSES.

In continuation of our recent description of apparatus for the above purpose we now propose to describe in detail Colonel Mangin's aplanatic projector, external views of which were given on page 408 of the current volume.

The reflector consists of a concavo-convex spherical lens of crown glass, the convex side M O N being silvered, and the concave side M' O' N' being struck at a smaller radius. Colonel Mangin has established by calculation the relation which should exist between the radii of curvature of the two surfaces and the index of refraction of the substance of which the lens is made, so that the spherical aberration due to refraction shall exactly counteract the spherical aberration due to reflection.

Colonel Mangin also determined the relation to establish between the radii of curvature of the two surfaces in terms of the index of refraction of crown glass (taken as the substance), so that O, the centre of the inner surface, might also be the principal focus of the aplanatic reflector. Consequently, if a luminous point be placed at O the rays will traverse the inner surface almost normally, and no light will, therefore, be dispersed by reflection from the concave surface of the lens.

The only divergence produced by this lens, when properly focussed, is that which is due to the size of the luminous point as compared with its distance from the centre of the silvered surface. This divergence cannot be avoided.

In the case of an ordinary spherical reflector there is much scattered light, and the intensity of the light varies consistently in the various portions of the illuminated area.

Those are great defects in a search light for war purposes: not only because the penetrating power of the light is so greatly diminished, but because it is often of such immense importance to direct the light upon an enemy while keeping one's own forces in darkness. These defects are overcome in the Mangin projector, the cone of light from which is accurately well defined and the intensity of the light in the various portions of the illuminated circle is practically equal, diminishing only according to the distance combined with the state of the atmosphere and to the angle of divergence.

Figs. 1 and 2 show the lamp and projector in sectional elevation.

The hood A is closed at the back by the large aplanatic mirror B, protected by the metal cover b. In the centre of the mirror a small portion is unsilvered, so that it may be used as a sight hole, through which to watch the carbon points. The front of the cage is closed by a window c, holding vertical panes of glass, sometimes flat and sometimes, when it is desired to obtain horizontal divergence, these window panes are of a plano-cylindrical horizontal section, the plane surfaces being external.

The hood is provided with openings to act as ventilators, which are covered with copper shields a. It is also provided with two trunnions, one of which is fitted with a worm and wheel e, actuated by the rod e_1 and handwheel e_2, and clamped by the nut and handle e_3. The hood is likewise fitted with a tube a_1 (see Fig. 1) carrying a prism and object glass, for producing an image of the side view of the carbon points.

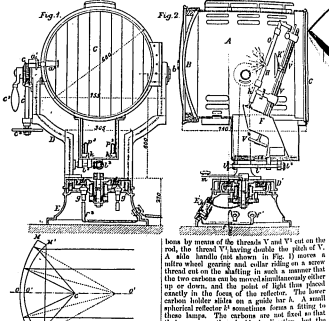
The supporting arms D are hollow, and the insulated copper leads p are carried up inside them. The arms are fixed to a table D^1, which rests on rollers that allow of horizontal revolution on the base-piece E of the apparatus.

Under the table D^1 is fixed a wooden annulus, to the bottom of which are attached two bronze rings, against which press the contact pieces f^3.

The leads from the dynamo are clamped to f^3. The positive current starts from f^3, whence it runs the following course: by copper strip f^2 through the insulating tube 2 to the ring d_1 to the arm D, to the side of hood to p^2, to the side of lamp (sliding contact) through lamp to p^3 to hood and other arm D and other ring d to p^1 and f^1 and back to the dynamo-electric machine.

Messrs. Sautter and Lemonnier, of Paris, are the sole manufacturers of this projector, and make four sizes:

One of 30 c.m. diam. and 160 mm. focal distance.
" 40 " " 240 "
" 66 " " 322 "
" 90 " " 710 "



The projectors are fitted with electric lamps which are regulated by hand, and are inclined at 20 angle of 20 deg. with the vertical, the top being the positive carbon. The lamp is ingeniously arranged so that the top carbon and its bracket can be racked backwards or forwards or sideways if required and then clamped. Also the handle l_1 moves the carbons by means of the threads V and V^1 cut on the rod, the thread V having double the pitch of V. A side handle (not shown in Fig. 1) moves a rather wheel gearing and collar riding on a screw thread cut on the shafting in such a manner that the two carbons can be moved simultaneously either up or down, and the point of light thus placed exactly in the focus of the reflector. The lower carbon holder slides on a guide bar b. A small spherical reflector l^2 sometimes forms a fitting to these lamps. The carbons are not fixed so that their axes exactly coincide in direction, but the upper or positive carbon is placed parallel to the lower carbon and slightly nearer to the lamp. In this manner, and on account of the inclination of the lamp, the centre of the positive carbon is caused to face towards the reflector (and in very large projection—over 80 per cent. of the light—is thus thrown in the desired direction. The electrical details of this lamp are substantially arranged last year as regards points of novelty. These lamps require the continuous electric current, and Messrs. Sautter and Lemonnier advocate the employment of the Gramme dynamo-electric machines driven direct on the same axis by three cylinder Brotherhood engines.

Most of the information in this paper has been taken from Messrs. Sautter and Lemonnier's pamphlet on this subject.

THE YOUTH'S COMPANION NEW BUILDING
COLUMBUS AVE. AND BERKELEY ST.
BOSTON, MASS.
THE LARGEST PUBLISHING HOUSE IN AMERICA DEVOTED EXCLUSIVELY TO ONE PUBLICATION

A Bulletin of Attractive Features provided for the Sixty-Sixth Volume.

1898

THE COMPANION announces for its 66th year no change of policy. What it has been in the past, what has commended it to more than half a million paying annual subscribers, it will continue to be, with all the additions in the interest, value and variety of its contents that experience and enterprise can suggest. The character of some of the special articles by famous writers secured for the forthcoming 66th volume, is indicated on the following pages.

It gives more reading matter of an excellent quality at a lower price than any weekly paper published. Every issue is well illustrated, and beautifully printed on fine paper. Each year it contains more reading than any $4.00 magazine, and the price is but $1.75.

For Young People it creates a desire for higher and better class of reading and every member of the family will discover articles of special interest for him or her. Though the paper is designed for young people, it has become known as a "National Family Paper."

Give a trial order to your Newsdealer for a copy each week for 5 weeks, so that you may test its merits and become acquainted with the paper. At the expiration of this short term we trust you will have been so well pleased that you will decide to have it continued in your family. Newsdealers also take Yearly Subscriptions.

No. 111. "Electric Light"

This is the last of nine scrapbooks containing clippings about electric lighting. The book covers the years 1881-1885, but most of the material is for 1884 and 1885. The pages are unnumbered. Approximately 70 have been used.

be really independent of that of the elongation.

4. Every vibration of the wire is accompanied by a generally very well marked variation of the resistance. In the majority of cases there was a decrease of resistance when the vibration was excited, and it was greater with harmonic than with fundamental vibrations. It was observed when the vibration was small. This latter law, however, needs confirmation.

The author considers it may be concluded, from his observations, that the variations of the resistance through tension are to be attributed not so much to a removal of the molecules from one another, so to a rotation, and consequent change of their mutual directions.

CHARSLEY'S IMPROVED VELOCIMAN—THE NEW PATENT TRICYCLE.

IT will be remembered by many of those who take a great interest in the bicycle when it was first introduced, that the original, some twelve or more years ago, that is, was called the "Velocimanicalcal bicycle" at several colleges in Oxford, at the same time patented a tricycle worked by hand, called the "Velocimen." Many used it with great comfort and pleasure. There was one great inconvenience however: the driver had to sit with his legs below the crank-axle, throwing a great part of his weight on the steering-wheel. The inventor rode many thousands of miles on it, and by the course of his journeys he always found that he could obtain the greatest speed, both consistent with ease and comfort, when the cranks happened to be parallel. It will be understood from this that the crank-axle was divided in the middle, making each wheel, with its crank, independent of the other, while the driver grasped the two cranks throughout each revolution.

When he found this, his great aim was to secure the constant parallelism of the cranks; and this, of course, was immediately effected by letting one wheel run in a box. The box sought to raise the seat of the driver above the crank-axle, and this was accomplished by introducing levers, which is described by the inventor as just that of rowing a boat, where one or both feet may be employed by the driver to urge forward the work of the hands. These we have the power of using any one, two, three, or all of the limbs at the same time, indeed, 10 different ways of driving are always at the option of the driver while the limbs not in use may be rested. The great advantage which follows from this rowing motion is the perfect steadiness of the wheels. The feet, when employed, act exactly in unison with the hands, and thus an immense speed can be secured. The machine has not been finished many days—in fact, the patent is not yet published. Mr. Charsley has, however, by very accomplished some wonderful performances with it already, especially in the way of mounting stiff hills. It travels backwards or forwards, and describes circles in its own length.

Before making the tricycle, the inventor's mathematical knowledge enabled him so to arrange the parts that the mechanical advantage of the combinations of the lever and wheel and axle should be a maximum, in other words, that the expenditure of muscular energy should be the least possible. Now it is made, it exactly ensures every expectation which he had formed. He calculated on 60 revolutions a minute with these wheels, which secures 15 miles an hour, with a little extra pressure he can increase the speed to 80 revolutions, or 20 miles an hour. Practice is continually showing us that these wheels might be driven with greater ease. How this would increase the speed if necessary figures will easily show. Mr. Charsley's first trial-trip with the machine just out of the shop was 84 miles long. It lay through Warwick to Stratford-on-Avon. He timed himself wherever he caught sight of a milestone, and found a mile took, on an average, 3 minutes; "Facile" minutes. The first mile exactly 20 years of age shows how easily the machine travels.

THE "FACILE" SAFETY BICYCLE.

SINCE our notice of the "Facile" bicycle, (p. 776, Vol. XXXI.) it has been improved in several minor details and in one important feature. The general design remains the same, but the crank and its attachment to the handle bevels are of a lighter and better shape, and by means of a screw-thread and nuts on the connecting rod or link, a machine of any given size can be adapted for use by riders having different length of leg. This feature will, we think, tend to bring the machine into considerable favour in certain quarters, especially where there are two or three riders in a family. When we passed Messrs. Starley's works the largest machine made was 48in., while the smallest wheels as high as 44in. have been adopted. We are glad to see by recent trials of the "Facile," it is not unlikely the makers will enter the field as builders of racing machines. With the 52in. wheel an average-sized rider can touch the ground while straddling the saddle, and with a 45in. one foot or the other is within a few inches of the ground, so that there is no fear of falling. With a machine of the latter size, well-known riders have kept up the usual club-run speed with their fellow members mounted on "ordies," and when a hill had to be negotiated had a decided advantage over the big wheels and direct action. At first sight it is concluded that the extra friction of the levers and links must necessarily militate against speed as compared with the ordinary bicycle, but the work being brought more directly under the rider's body is found to be an advantage nearly, if not quite, counterbalancing the disadvantage of the extra friction. The fact that a 48in. machine has been driven on a track one mile in 3m. 28s. shows that there is speed in the "Facile" as well as safety. We need not, when to this is added the fact that hills may be mounted and ridden down with comparative ease, that the "Facile" has a decided advantage over a brake without touching its virtues, be seen that there is a large class to whom such a bicycle commends itself. We see it announced that the telegraph authorities of New South Wales are about to mount their messengers on velocipedes of the tricycle type, and they expect to save about £500 per annum in the cost of forage alone for Sydney; but we think it a mistake to adopt a machine which runs on two tracks, when one equally safe can be had that will run on one track. The "Facile" is at length becoming known throughout the country, and the better it is known, the better it is liked.

THE BECQUEREL LECTURE.

THE Faraday lecture was delivered by Prof. Helmholtz last week, by the theatre of the Royal Institution, before a brilliant audience. Prof. Roscoe, as president of the Chemical Society, introduced the lecturer. After a few words of introduction, the chairman handed Prof. Helmholtz the commemorative medal in palladium, and a duplicate in bronze, and the lecturer then proceeded with his discourse. The lecture consisted of a sketch of the way in which Faraday's discoveries had been connected directly or indirectly with questions touching the nature of electricity. The facts which he found were universally known. Nevertheless, the fundamental conceptions by which Faraday was led to these most-admired discoveries have not been received with much consideration. His principal aim was to oppose in his new conception the notion of electricity as a kind of hypothetical substance and force. This would really a progress in general scientific method, especially in purely science from the last remnant of metaphysics. Now that the mathematical interpretations of Faraday's conceptions regarding the nature of electric and magnetic force had been given by Clerk Maxwell, we see how great a degree of acuteness and penetration was really hidden in the words of Faraday, which were sometimes used in vague or obscure; and it was astonishing to the highest degree to see what a large number of general theorems, the fundamental ideas of which comprises the highest powers of mathematical analysis, he had found by a kind of intuition, with the help of mental experiment, without the help of a single mathematical formula. Almost the whole of Faraday's researches, although containing a great number of perfectly accurate and demonstrated questions, were directed to the solution of the fundamental problems of electricity. Principally, the one more regarding the nature of electricity, which he called the theory of Volta-force; the other, to the more exact knowledge of chemical force, or those which act from molecule to molecule, and the relation between these and the first. The great problem which Faraday called the theory of Volta-force was the existence of the working electricity or without any intervening medium. He took up the old and long-known of the motions of magnets under the influence of electric currents, and discovered "induced" currents, and later, in 1846, he discovered the phenomenon of diamagnetism, which gave indications of a "polar force," instead of all so-called permanent "matter" in magnetism. Further, with quite wonderful sagacity and intellectual precision, Faraday performed in his brain the work of a great mathematician without using a single mathematical formula. He was led to the idea that the whole space system of tensions and pressures caused by the dielectric and magnetic polarisation of space which surrounds electrified bodies, magnets or wires conducting electric currents, all the phenomena of electro-static, magnetic, electro-magnetic attraction, repulsion, and induction which take place in the neighbourhood occurring at all in these active electrified or charged. Professor Helmholtz then dwelt at length on Faraday's work in connection with electric and chemical force. Taking up the electro-chemical theory of dissolics, he carried out experiments which showed that the view was erroneous which supposed that the quantity of electricity collected in each atom was dependent on their mutual chemical affinity. The result of these researches was, that—if we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid ascribing that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity. As long as it remains in the body of the electrolyte liquid each atom remains united with the corresponding quantity of equivalents. At the surfaces of the electrodes decomposition can take place if there is sufficient electromotive power, and then the atoms give off their electric charges and become electrically neutral. Professor Helmholtz then passed on to a consideration of the forces which are called into close motions of considerable matter going on in an electrolyte. The author showed by calculation that chemical affinity and electricity are one and the same. In concluding, he said that it seemed to him best, to take as his portion of the review of Faraday's work, what treasures, from a chemist's view, still lay hidden in his work, though he did not know the precise formulation of the law of energy applied to the electrolytic act, nor of the laws which regulate the distribution of electricity in space, as well as in considerable isolated quantities of electric current or flowing conductors.

THE BRUSH SYSTEM OF ELECTRIC LIGHTING.

By CHARLES F. BRUSH, M.E.

The Dynamo-Electric Machine.

THE most prominent peculiarities of the Brush dynamo-electric machines are embodied in the armature, the arrangement of field magnets, and the commutator. The armature consists of a ring of soft cast iron, revolving in its own plane. This ring is composed of two or more parts, each encircling the shaft. After a few words of introduction, the chairman handed Prof. Helmholtz the commemorative medal in palladium, and a duplicate in bronze, and the lecturer then proceeded with his discourse. The lecture consisted of a sketch of the way in which Faraday's discoveries had been connected directly or indirectly with questions touching the nature of electricity. The facts which he found were universally known. Nevertheless, the fundamental conceptions by which Faraday was led to these most-admired discoveries have not been received with much consideration. His principal aim was to oppose in his new conception the notion of electricity as a kind of hypothetical substance and force. This would really a progress in general scientific method, especially in purely science from the last remnant of metaphysics. Now that the mathematical interpretations of Faraday's conceptions regarding the nature of electric and magnetic force had been given by Clerk Maxwell, we see how great a degree of acuteness and penetration was really hidden in the words of Faraday, which were sometimes used in vague or obscure; and it was astonishing to the highest degree to see what a large number of general theorems, the fundamental ideas of which comprises the highest powers of mathematical analysis, he had found by a kind of intuition, with the help of mental experiment, without the help of a single mathematical formula. Almost the whole of Faraday's researches, although containing a great number of perfectly accurate and demonstrated questions, were directed to the solution of the fundamental problems of electricity. Principally, the one more regarding the nature of electricity, which he called the theory of Volta-force; the other, to the more exact knowledge of chemical force, or those which act from molecule to molecule, and the relation between these and the first. The great problem which Faraday called the theory of Volta-force was the existence of the working electricity or without any intervening medium. He took up the old and long-known of the motions of magnets under the influence of electric currents, and discovered "induced" currents, and later, in 1846, he discovered the phenomenon of diamagnetism, which gave indications of a "polar force," instead of all so-called permanent "matter" in magnetism. Further, with quite wonderful sagacity and intellectual precision, Faraday performed in his brain the work of a great mathematician without using a single mathematical formula. He was led to the idea that the whole space system of tensions and pressures caused by the dielectric and magnetic polarisation of space which surrounds electrified bodies, magnets or wires conducting electric currents, all the phenomena of electro-static, magnetic, electro-magnetic attraction, repulsion, and induction which take place in the neighbourhood occurring at all in these active electrified or charged. Professor Helmholtz then dwelt at length on Faraday's work in connection with electric and chemical force. Taking up the electro-chemical theory of dissolics, he carried out experiments which showed that the view was erroneous which supposed that the quantity of electricity collected in each atom was dependent on their mutual chemical affinity. The result of these researches was, that—if we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid ascribing that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity. As long as it remains in the body of the electrolyte liquid each atom remains united with the corresponding quantity of equivalents. At the surfaces of the electrodes decomposition can take place if there is sufficient electromotive power, and then the atoms give off their electric charges and become electrically neutral. Professor Helmholtz then passed on to a consideration of the forces which are called into close motions of considerable matter going on in an electrolyte. The author showed by calculation that chemical affinity and electricity are one and the same. In concluding, he said that it seemed to him best, to take as his portion of the review of Faraday's work, what treasures, from a chemist's view, still lay hidden in his work, though he did not know the precise formulation of the law of energy applied to the electrolytic act, nor of the laws which regulate the distribution of electricity in space, as well as in considerable isolated quantities of electric current or flowing conductors.

THE BRUSH SYSTEM OF ELECTRIC LIGHTING.

By CHARLES F. BRUSH, M.E.

The Dynamo-Electric Machine.

THE most prominent peculiarities of the Brush dynamo-electric machines are embodied in the armature, the arrangement of field magnets, and the commutator. The armature consists of a ring of soft cast iron, revolving in its own plane. This ring is composed of two or more parts, each encircling the shaft. After a few words of introduction, the chairman handed Prof. Helmholtz the commemorative medal in palladium, and a duplicate in bronze, and the lecturer then proceeded with his discourse. The lecture consisted of a sketch of the way in which Faraday's discoveries had been connected directly or indirectly with questions touching the nature of electricity. The facts which he found were universally known. Nevertheless, the fundamental conceptions by which Faraday was led to these most-admired discoveries have not been received with much consideration. His principal aim was to oppose in his new conception the notion of electricity as a kind of hypothetical substance and force. This would really a progress in general scientific method, especially in purely science from the last remnant of metaphysics. Now that the mathematical interpretations of Faraday's conceptions regarding the nature of electric and magnetic force had been given by Clerk Maxwell, we see how great a degree of acuteness and penetration was really hidden in the words of Faraday, which were sometimes used in vague or obscure; and it was astonishing to the highest degree to see what a large number of general theorems, the fundamental ideas of which comprises the highest powers of mathematical analysis, he had found by a kind of intuition, with the help of mental experiment, without the help of a single mathematical formula. Almost the whole of Faraday's researches, although containing a great number of perfectly accurate and demonstrated questions, were directed to the solution of the fundamental problems of electricity. Principally, the one more regarding the nature of electricity, which he called the theory of Volta-force; the other, to the more exact knowledge of chemical force, or those which act from molecule to molecule, and the relation between these and the first. The great problem which Faraday called the theory of Volta-force was the existence of the working electricity or without any intervening medium. He took up the old and long-known of the motions of magnets under the influence of electric currents, and discovered "induced" currents, and later, in 1846, he discovered the phenomenon of diamagnetism, which gave indications of a "polar force," instead of all so-called permanent "matter" in magnetism. Further, with quite wonderful sagacity and intellectual precision, Faraday performed in his brain the work of a great mathematician without using a single mathematical formula. He was led to the idea that the whole space system of tensions and pressures caused by the dielectric and magnetic polarisation of space which surrounds electrified bodies, magnets or wires conducting electric currents, all the phenomena of electro-static, magnetic, electro-magnetic attraction, repulsion, and induction which take place in the neighbourhood occurring at all in these active electrified or charged. Professor Helmholtz then dwelt at length on Faraday's work in connection with electric and chemical force. Taking up the electro-chemical theory of dissolics, he carried out experiments which showed that the view was erroneous which supposed that the quantity of electricity collected in each atom was dependent on their mutual chemical affinity. The result of these researches was, that—if we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid ascribing that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity. As long as it remains in the body of the electrolyte liquid each atom remains united with the corresponding quantity of equivalents. At the surfaces of the electrodes decomposition can take place if there is sufficient electromotive power, and then the atoms give off their electric charges and become electrically neutral. Professor Helmholtz then passed on to a consideration of the forces which are called into close motions of considerable matter going on in an electrolyte. The author showed by calculation that chemical affinity and electricity are one and the same. In concluding, he said that it seemed to him best, to take as his portion of the review of Faraday's work, what treasures, from a chemist's view, still lay hidden in his work, though he did not know the precise formulation of the law of energy applied to the electrolytic act, nor of the laws which regulate the distribution of electricity in space, as well as in considerable isolated quantities of electric current or flowing conductors.

fifty revolutions per minute, in its normal magnetic field, the electro-motive force developed in the conductor is sufficient to maintain its normal volume of current through an external resistance, including the field magnets of the machine, of fully eighty times as much as a copper wire twenty times as great in diameter. No other form of dynamo-electric machine has ever been made to approximate with this. The current operates from sixteen to eighteen powerful electric lights arranged in a *single circuit*, going to each an arc of about two millimeters length. The resistance of these arcs averages about four and a half ohms each, as shown by many careful measurements of different lights during the past year. This makes a total resistance included in the magnetic field of 72 ohms, the resistance of which is, however, quite small, and will be given further on.)

The bobbins of wire on the armature of the Brush machine are not connected together in a single circuit, but each pair of diametrically opposite bobbins only are connected together, thus forming a set of the commutator bar formed of two only of the segments of the commutator cylinder and attached to diametrically opposite segments thereon, which segments are not connected with any other bobbins. Thus each pair of bobbins is entirely independent of any other pair. In this arrangement, which secures important advantages, the Brush machine again differs radically from the Gramme and all similar continuous-current machines.

The commutator consists of four separate rings of metal, each ring consisting of two nearly semi-circular segments, whose ends, on one side, are separated by a considerable space. This space is occupied by a piece of metal attached to an adjoining ring, and known as an "insulator." It is insulated by an air-space from each of the segments between which it is placed. The two insulators, of the segments being simply separated by a single air-space. The office of the "insulator" is to separate either of the brushes which collect the currents from the commutator, from both segments during a certain interval, and to unite in each revolution of the commutator. The insulators are placed at right angles to the axis of the armature which are connected with the pair of segments are not only out of the general line of cut, but are open-circuited themselves, so that no current can circulate in them. Each pair of bobbins on the armature is thus provided with a commutator ring, and the segments of this ring occupy the same angular position with regard to their respective bobbins as the brushes occupy with regard to those attached to the other pair of bobbins.

It will now be seen that only one pair of armature bobbins is cut of the general circuit at one time; and this is made to occur when the said bobbins are at and near the neutral points of the armature, and are not in a condition to contribute to the general current. Now, if it were not for the "insulators" mentioned, the idle bobbins would afford a easy passage for the current from the active bobbins, and, like dead-beat bobbins of the armature.

The Gramme form of commutator, which is employed for the production of continuous currents in all machines other than the Brush, involves serious disadvantages, which the Brush form of commutator is free. The practical difficulty arising from the use of the Gramme form of commutator is, wire, wears at and near the neutral points of the armature, constitute little or no useful effect: but the current from the other bobbins must pass through them in order to reach the brushes, thus experiencing a considerable and entirely useless resistance, and owing to the opposite directions of the currents in the bobbins on the two opposite sides of the neutral points, the current is arrested by passing through the idle bobbins, and strongly to produce "sensorial" shocks in the armature where the neutral points should be: thus interfering seriously with the proper distribution of the armature's magnetism. It may be argued that this latter disadvantage is obviated by allowing each of the brushes to exchange with two sections of the commutator, corresponding to bobbins on both sides of each neutral point: this is, no doubt, true to some extent, but another and perhaps worse evil is thus introduced: the bobbins corresponding to the commutator sections connected by each brush are short-circuited by these two contacts and brushes occur with each brush in each revolution, and the consequence is that, in different flags, we find but one-fourth of the whole current is received at one time.

Further, the use of the subdivision appears to be impracticable with the Gramme form of commutator, while it may always be employed on the Brush commutator with great advantage. Thus the durability of the commutator is much increasingly greater than that of the other. When necessary, the wearing segments of the commutator may be replaced by duplicate pieces in a very few minutes by any mechanic.

The Lamps.

There are of very great simplicity of construction: insuring ease of management, safety against informal derangement, and wearing out but slightly of working; the double magnet circuit conveying currents of opposite direction, by means of which any number of lamps may be ejected in a single circuit, without any change of strength in the main current, automatically open-circuiting any lamp offering an abnormally great resistance, owing to the final consumption of its carbons, or other cause, will, without any change of strength in the main current, automatically short-circuit the said lamp, and thus preserve the integrity of the general circuit; the small size of carbons, burning successively, without the intervention of any attendant, and thus insuring a steady light and economy; the maintenance of the light for any desirable length of time without requiring attention; lastly, the absence of any adjustment to be made by the attendant other than placing the carbons.

Three lamps consists mechanism or similar mechanism of any kind. The movement of the upper carbon is effected by a simple clockwork train, a description of which, as applied to this lamp, is carrying the carbons. When the lamp is in operation, one side of the clamp is lifted by magnetic action; this causes it to grasp and raise the rod, and thus separate the carbons. As the carbons burn away, the magnetic action diminishes, and the clamp rod and more gradually downward, maintaining only a proper separation of the carbons; lastly, the absence of any adjustment to be made by the supporting fixe from which it slides, any further downward move will at once release the rod and allow it to fall through the clamp, until the latter is again brought into action by the increased magnetism due to the shortened arc between the carbons. In continued operation, the normal condition of the clamp is to contact with the upper support, the action of the ascending magnet being sufficient to overcome the descending one. If, however, the rod accidentally slides in the clamp, it will instantly and automatically be raised again, as at first, and the carbons thus restored to their proper relation to each other.

Each magnet bobbin is first wound with a few layers of coarse wire, through which the main current passes, and then with a fine wire of high resistance. Over this coarse wire another wire is wound, the length of fine wire, having its ends connected with the terminals of the lamp, but in such a manner that the electric current shall pass through it in a direction opposite to that in the coarse wire coil. Thus the fine wire forms a secondary circuit of high resistance through the lamp, which should be independent of the arc between the carbons, and is in fact a shunt to the arc. Under the normal conditions of the current the latter is the case, but the fine-wire bells will constantly tend to neutralise the magnetism produced by the coarse wire or principal helix. The number of convolutions of the fine-wire bells and its resistance are so proportioned to the number of convolutions in the coarse wire helix, and the resistance together with that of the lamp, that, with the magnetising power of the fine-wire helix, the magnetising power of the former. Considering the small amount of current which passes through the fine-wire wire when joined one per cent. of the whole current, its magnetic power is very considerable, owing to the great number of convolutions.

Now, when a number of regulators provided with these double magnet coils are placed in a single circuit, great uniformity of action will be maintained, owing to the peculiar function of the secondary bells. Thus, when any lamp gains more than its normal arc, the resistance of its main circuit is increased; more current is consequently diverted through its secondary helix, and the retarding power of the latter is increased, causing the clamp to approach its normal position. If an arc becomes incident, its resistance is reduced, and more current is diverted through its correspondent secondary helix; consequently, the working magnetism in that lamp is lessened, and the carbons are drawn further apart. This it will be seen that, although the total strength of the current upon passing a large number of these lamps does not vary, the distribution of the current is automatically under the agency of varying conditions, precisely as though it were the only lamp in the circuit.

In practice, the resistance of the fine-wire bells or helices in each lamp is rather more than four hundred and fifty ohms; while the resistance of the coarse wire, various connections, carbons, and bells in each lamp used with the sixteen-light machine is about four and one-half ohms. Hence not more than one-fiftieth part of the current is diverted from the arc. The resistance of the coarse-wire bells, carbons (copper-coated), connections, &c., in each lamp is very small.

To determine this resistance, sixteen lamps were connected in series in the usual manner, about two hundred feet of No. 16 copper circuit wire being used. Full-length carbons were also placed in the lamps, and the upper carbons of each pair were adjusted by means of a screw at the top, so as to project to each carbon, the distance of the whole arc was then measured, and found to be 2·20 mm., showing a resistance for each lamp, with its carbons, of 0·11 ohm. This is 2·2 per cent. of the whole resistance of the lamp when in operation. To this low must be added the one per cent. due to that minute current diverted from the arc by the secondary helix, making a total of 3·2 per cent. of 225 ohms, the total resistance of the lamp, or 7·2 ohms, a very slight energy absorbed in each lamp appears in the arc between its carbons.

The shunting or short-circuiting device in each lamp consists of a small magnetic core, surrounded by a coarse and a fine-wire helix, similar to those of the working magnet. Its current passes through the coarse wire until the magnet which it surrounds is sufficiently energised to lift its armature, with the contact piece, which forms a part of the short circuit established through the lamp. The fine-wire helix of the shunt is in the circuit of the fine-wire galvanometer below referred to work. During the normal operation of the lamp, this fine-wire helix exercises a magnetising influence on the shunt magnet, but its attractive action is only to a certain degree of force, not sufficient to lift its armature. Should, however, the arc of the lamp increase in length, or from their failing properly to feed together, the arc between them becomes considerably lengthened, the fine-wire helix exercises a great resistance in the lamp, a greatly increased current will be shunted through the fine-wire helix, the iron core of the latter will raise its armature, and thus short-circuit the lamp, the carbons of which will, in consequence, approach each other.

Evidently, when the short circuit is closed as above, the current will continue to circulate in the wire helix, and the magnet would drop its armature if it were not for the fact that the armature not retained by some means other than the magnetism of the wire helix; but it will be remembered that the coarse-wire helix surrounding the shunt magnet is in the main circuit, and that the current passes in the contrary direction to that in the fine-wire helix. Hence, when the short circuit is established, which any lamp becomes extinguished, the coarse-wire helix always present when many lamps are burned in a single circuit. It is believed that it would be without any change in the strength of the general current, supposing a number of many lamps were put into the great merit. No effect is produced in the fine-wire galvanometer by the extinction of a lamp, as the latter is not in the circuit of the galvanometer. The regulation of the current through the lamp is effected by the separation of the carbons when the arc is established, and the approach of the carbons when the arc is extinguished. The action of the lamp consists in the attraction of a soft iron bar, which is drawn into the coarse wire helix, and the resistance of the carbons is thus increased. The carbons are held apart by the repulsion of the two magnets, which are placed in the circuit of the lamp, and the upper carbon is lifted by means of a clockwork train, actuated by a weight. The latter is wound up by means of a cord passing over a pulley on the axle of the train, and is connected with the upper carbon holder. The clockwork train is set in motion by the attraction of the

Pesti Napló. August 22, 1882.

— Edison-féle villamos világítás a fővárosi közkönyvtárban. A Gánz- és társa gyár mérnöket hóban fő tett próbát a villamos világítással a fővárosi táviróhivatal géptermében. Ezen két héti próbát a mult héten kedden befejezték. A nevezett gyár villamvilágítási osztályának vezetője által működtetett többféle lámpával tett kísérletet. A mint a Zipernowsky-féle lámpák a mult héten eltüntek a központi táviróhivatal most fönyes berendezéseit temdőbl, P. t. k.s Ferencz, a fővárosi telefon-vállalat igazgató tulajdonosa azonnal megkezdette a berendezési munkálatokat, a vgy a géptermében működő tiezti személyzet, mint az intézet vezérférfiai élénk érdeklődéssel néztek az első próba elé. Május 30-ára, szombata közen lesték a bereudezés egy részével; a mennyiben a fiert és női távíró-géptermében összesen 80 db. különféle kínézésű Edison-féle villamos lámpa már — a mint egyelőre nevezik — el volt helyezve, a gőzgép, melyet elektro-dinamikus gép, fel volt állítva. Estefelé 8 óra után pár perczczel a termek már meg voltak világítva. E próbára eljött Puskás Ferencz bányás is Párisból. Ezen kivül sok látogató volt. Míg a Zipernowsky-féle nagy ívlámpák világították mellett az egész terem szépségében lebeteri gyönyörködni a sok valóban fényes elvarázsoló, meglepő benyomást tettek a szemlélőre az első pillanatban : addig ezen czélszerűbp elosztott apró, kedves ívlámpák és kisebb nagyra könnyű kitatni ; hanem az egyes távirógépek közvetlen közelségében, ernyőről elátva, mintegy lefolyozott szerőnyeg, tűntek fel az emberi szemnek. Ha meggyőződtünk, az egyes gépeknek hiv szépen, kellemes világítás mellett, lehetett dolgozni, hahár két gépre volt egy lámpa alkalmazva a nagyobbakból. A személyzet legnagyobb része ezeket megelégedett az uj világítással s e rendszerben egyáltalában több remónyt kötnek ; mert hiszen az eddigi gyakorlati tapasztalatok szerint ezen izzó lámpák legalkalmasabbnak a távíró hivatal czéljaira. Itt nem azról van szó, hogy egy helyen nagy, vakitó fényt fejlesszenek, az ternmi a annak állandó személyzetét a nagy közönségnek mutogassuk, hanem hogy a rosszgásvilágitás, a nagy hőség és még rosszabb levegő helyett szép világító szervezeti hivatalnoki haron esszünye legyen. Es ez leginkább elérhetőnek látszik ezen. Érdemleges birálatot ugyan most még korán ezeknek mondani; mert a czél az a helyi körülmények, távírók helyes, czélszerű kiakasztásától sok függ ; de mi azt hiszszük, a mennyire az e téren tett tapasztalatokra támaszkodhatunk, hogy ebből állításunk és találvatnak nem fog csalni. Különben a világítási mindenről lesz alkalmunk meggyőződést szerezni s erről a közönségnek lehen értesíteni. A próbák ugyanis 2 hónapig fognak tartani ; a fentemlített helyiségeken kivül a Puskás és a közmunka- és közlekedésügyi minisztérium távíró-szakozatában közöttük kötött egyezmény szerint a posta-távíró palotában még a következők lesznek villamossággal megvilágítva : a távíróhivatalban földszint a távíratok : földszinti szolgáló terem, annak előcsarnoka, valamint az fpdlet koronaherczeg-uteza felől levő előlépcsője egészen a lámpák emeletig ; a főpostánál : földszinten a zsidra-uteczai részen levő valamennyi levélfeladási helyiség, az első emeleten az irányító terem s az a mellett levő helyiségek és végre a zsidra-uteczai sarkon levő előlépcső egészen a harmadik emeletig.

Edison és az elektrikus világitás.

Edison már sálunk sem' mithikus 'alak,' mint volt kezdetében, midőn hire jött számos rendkivüli találmányainak, mint a phonographnak, edison-lámpának, stb. Itt látjuk már kiküzdtnek szivól-szivre a mesés találmányokat.

A sznad egyik legtcrkésebb alakja körülbelül 36—37 éves, a középtermetnél magasabb, sőtben termetiel, hallatlan kitartással a munkában, mely tudományosságával a mathematika, vegytan, természettan terén és speczialista a villanyosság kezelésében, kombinálásában.

Kiterjedtsnek jellemzéseo elég lesz elmondani, hogy miképen szerkesztette ő híres elektrikus lámpáját. A beszerzőnk almájának megszerzése, Herkules tizenkét hőstette semmi'ahhz a tanulmányozáshoz, utazáshoz, kölcsönzéshez, a mit Edison elkövetett a végett, hogy végleg megállapítsa : mit alkalmazzon a lámpában a fény terjesztésére ?

1878-ban, mikor Edison neve már bejárta a világot, különösen a phonograf ró'vén, egyszer azt mondja neki egy barátja, Draper: Mi volna abból, ha te most a villamos világitás tanulmányozásra adnád magadat s — Igaz a ! — felelt Edison szárazozotan.Aztán bemeuve laboratoriumába, azonnal egész komolységgel elkezdi a studiumot, abban hagyva félben levő munkáit, találmányait. — Már neki meg volt a maga czélnje és a tervezetet nagyobb vonásokban elkészité. Ha a villamosság fényt produkál, meg kell találni az eszközt, hogy állandó világosságot is terjesszen, még pedig no csak a közterekeu, utczákon, nagyobb helyiségekben, hanem a házak belsejében is. Az czeme tehát az volt, hogy az olcsót, petroleumot és gázt helyettesitseni kell a villamosság által ; ezt már első tudjuk állitani : most hát az a feladat, hogy egy készülékot konstruáljunk, a mely a villamosságot a jelzett czélra alkalmassá tenni, olyat, a mely mintegy kanalizálja a villamosságot és azt elvezesse hárhevá, mint a czévek a gázt.

Ez nem volt könnyü feladat.

A használatban levő rendszerek, a melyek oly jóknak tüntek fel, illvalón rendszerek voltak. A melyeknél a szonet pótolgatni kellett, mint a petroleumnál a lámpa-belet, Edisonnak gyarlóknak látszottak. — Mért ne lehetne használni a platina drótot, mely a villamos fólyam által világossággá terjesztett ? Ez oly erős rugyogó fényt ád. Próbát tett a platinával és az is használhatónak mutatkozott, a villan-folyam alatt, de mihamar elolvadtak.

Ezután kisérletet tett másféle szilárd érczekkel is, melyeket ugyszólván elvarázsltásunknak mondtak ; a melyek többnyire a platinával együtt találtatnak, ilyenek: a ruthenium, palladium, rhodium, osmium, iridium stb. Ezek közül mindegyik megjelentésre ritka. A leggazdagabb laboratoriumokban csak apró adagocskákat lehet belőlök látni, olyatzo egy-egy tognatják meg őket ; ez rhodium, ez meg osmium stb. A mint Edison a valamennyit, a m végezte érezeket keresztül akarta próbálni, nagyon megakadt a rhodiumnál. Nem talált egy pozsemmiyik sem a chemiai anyagokkal kerekedő bolloknál. Itt tehát az Egyesült-Államok egy híres mineralogistájához, a kiről gyújtőmárgye van érvényben, a mélő nép szerelmére három évet, urasi, töltött nekem egy kis rhodiumot ; majd megszolgálom.«

»Rhodiumot ? — felelt a tudós, — nem volna gáthatnék, de fogadok rá, hogy az egész Egyesült-Államokban nem talál ön annyit az érczből annyit, hogy egy forsknzat czélnthesson belőle.«

— No hiszen majd meglátjuk — szólt Edison a levél olvastatása után.

Találtak már darabon platinát elegot ; ott rhodiumnak is kell lenni.

Utaszik el ön rögtön — szólt azután Edison egy segédjéhez, — vigyen magával munkásokat és mindent a mi szükséges, azután teromtsen nekem rhodiumot a föld alól.

A kikelőtét azonnal utra kel vagy 50—60 munkással, a kiket busás fizetéssel lát el, a találandó aranyat mind nekik ajándékozná a nuhány hét multva ; sőtazonnal vagy bat kilogramm rhodiumot és hazavissi Edisonnak.

Edisonnak a legelső gondja pedig'az volt, hogy legyakkott egy kilogrammnot a rhodiumból e elkildte a hires mineralogistának, hehtozyfejtsék, hogy még sem olyan nagy ritkaság az az ásvány.

Hanem lás6 ez a rhodium, so a platina, so az iridium, so más érez — fiazáru tóbb, mint meglep jő sikrrt experimentálásnak — nem vezette Edisont végleges megoldásra.

Ekkor azután megint csak visszatért próbálgatásával a szénre. Próbálta szenesiteni a papirost, a bristol cartont, a ruhát, mindenféle fa gallyát, a siten tudná mi mindent ! Segédeit alkalmazta ez ópus egy, mint a rhodium felkeresésére — ogész Amerikát, Ázsiába, különösen Chinába és Japánba, hogy bornmak onnan neki minden ismert és ismeretlen növényből mutatóbo, a hambusz, különösen annek rostjai létezoitak Edison előtt alkalmasaknak a kivánt czélra. Tárgyleg csakugyan a japáni bambusz rostjait használta azután a lámpáihoz.

A szenesitett rost hajlit alakjában van egy kis légmentes golyóban elhelyezve, a csak részli beszáritni és elektrop os folyamot, azonnal vakitó fényben jrik, a mely fényt azonban egy alkalmazott készülékkel mindenfülékpen mérsékelni lehet.

Most azután már Edison minutiosus kidolgozása folytán olyan tökéletességre van vive az elektromos lámpa, hogy lehet belőle csillárokat épen egy vendéglőtani, mint a hogy használhatja az otte dolgozó emberek, mindenütt ugyanoly erőteljes világosságot szolgáltat, ellyen a gáz fölött az, hogy az egészségre semmi káros behatással sincs, s még a gáz annál érzékenyebbtelen hőséget árasz, addig az elektromos fény egy csapnyi szem változatja a sárt fölött nem érez.

Az Edison-féle világító rendszer jelességeről különben mindenki meggyőződhet szerezhet magának a központi távíró hivatalban és Szilassy vendéglőjében. Valamint oté a hivatal kar, ugy itt a nagy vendégsereg csak dicsérettel emlékezik meg róla.

A hahéta mai világban azonban nincs az a jó, a mely ellenében más nem állana elő nnal, az ime jobb ! Ez: tesni a Gánz-féle társaság midőn kiáll a nyilvánosság terére A nemzeti zászlóhoz, nélkülözhetetlen világitási rendszerét világgal, és hogy a maga részére hódítsa a nagy közönséget, azt adja ki jelszóul, hogy ez »hazai találmány.«

Ha valaki, ez valóban azok, kik készséggel nyujtanák oda neki a babért, ha csakugyan egy rangha volna helyezhető az Edison-féle világitásnál vagy azt csak meg is közelitené. Fájdalom azonban nem tehetjük, mert a tompa világosság fogalmat a »fény« nevével nem illethetjük. Hozzá járul ehhez még az, hogy a mellett, hogy nem »jobb«, de nagy nem is »hazai találmány.« Nem egyéb az, mint külföldi utánzatból helytelenül összekombinált *fényforrás* fény szükül és meglehetősen forkand.

Nem a részrehajlás mondatja ki velünk az itéletet; hanem a meggyőződés, melyet hathatósan támaszt a közvélemény, mely azt mondja, ha eddigi világitási módunkat újabbal akarjuk pótolni, válasszunk a legjobbat, a legmegbizhatóbbat, és mely gyakorlati alkalmazhatóságának már nem szorul kiséletre, hanem egész tökéletességében ajánlkozik a használatra. Ilyen pedig Edison elektromos világitási rendszere. P.

THE SUNDAY HERALD

You manuscript of the Nijne Tavnire tale' ictan a step in advance of any' manuscript in the country, as evidenced sufficient for fighting purposes. Edison's light is the best light in the world exclusively. The Savoy in London was the first Theatre to be illuminated with the incandescent light, and the Paris Opera House is the second Theatre, also illuminated by the same adopted this system; but the Paris Opera House is not illuminated as well as the Savoy Theatre in London. However, the Paris Opera House is illuminated with the Edison system for its decorations, and the Edison light is the best in the world for decorations. In the Savoy we have about three chandeliers pendent from the dome, 360 lights in each chandelier, and 12 lights on the walls of the auditorium on each tier or tower floor and six in the balcony, 37 tiers in all. The stage is lighted by the Edison system, and the footlights are all electric lights. The chandeliers were manufactured in New York for the Edison Co. of Paris, but, on account of the war, were not sent over—they are now in the Edison Co.'s warehouse in Paris, and will be put up shortly. In the Opera House there will be about 1,200 lights. Mr. Edison himself has planted the dynamos in the cellar, but will personally superintend the plants.

ELECTRICAL WONDERS.

INTERESTING RESULTS OF THE VIENNA ELECTRIC EXHIBITION.

Among the many startling electrical scenes at the Vienna Electric Exhibition is Messrs. Lauterwasser and Bitter's new thermo-electric battery. The principle of these batteries is the direct transformation of heat into electricity without passing through the intermediary stage of work, as in the case of the employment of a dynamo. Great promises were held out here three or four years ago, on the construction of Clamond's so-called heated thermo-electric screw, that this most important problem was advancing toward a solution, but it never came; but nothing further was heard of it, and the clearest whatever has been made since is by the above.

Messrs. Lauterwasser and Bitter exhibit a thermo-electric battery, which presents the form of an ordinary screw, and can be used in such. It consists of thirty superposed concentric cylinders of German silver, the rings being fastened from one another by means of asbestos. The external cylinder of an either of two electrically opposite metals that the pointed nut being completed the inventor used the nut and its exact composition, which forms an air-tight cylinder, or ear heating this alloy an electric current is generated. The remaining cylinders are placed in the center, and, of considerable space between them, form the communicating rings, so that the heating of the alloy of one cylinder draws, and the communication by which the alloy is heated does not exceed 300 degrees to 600 degrees C. Both the inside ring and the outside cylinder are connected, the whole or the part of the current being passed. The current has an electric motive force of twenty volts, and twenty current resistance. The battery is attached for gilding, and has been used in an important point of the above, as the case in which, in that which is not of air, as that current power can be established by using a number of accumulators sufficient for Siemens lighting purposes, or to drive a small motor for doing electric work, without any extra expense.

Mr. Bitter's second machine was thermo-magnetic. There are three telephone rooms for central reproduction. In one of these the Berliner telephone, established by Mr. J. Bettner, of Hanover, reproduces the concert of a military band performing at Hengelmann's restaurant in the Prater. The receiver is an ordinary bell. The transmitter is the exhibitor's invention, is of very simple construction and admirably adapted for ordinary transmission of speech. The conversation can be carried on in the largest room of the house, and every note is repeated with great clearness. The microphonic transmitter has caused the "chaperon telephone," with the "sleeper of silence," the "polyphonic" telephone all the other telephonic stores at the Palace (see correspondence of yesterday), and there can be no doubt that this will be received by the fact that with the microphonic transmitter no sounding on the part of the listener is necessary, valid with the receiver to produce the subscriber can always considerably. Within the room in order to be heard; Siemens's transmitter consists of a small hard carbon point, placed between two conical screws; the carbon point which forms a small, specially hard carbon disk which is connected to a variable diaphragm, and the whole complete contact is made without friction. The transmitter is only fixed at the back of the receiver is the microphonic case, and on electing the small pointed screw the point is carbon which is opposite to the carbon disk, fixed to the membrane. The second point is fixed to the back of the receiver case, but the membrane, and, but also as a regulator, in case of the vibration of the membrane being too strong or not strong enough. The transmitter battery consists, as a rule, of two Leclanché element.

THE TRANSMISSION.

The reputation of the exhibition, please judged at the restaurant was clear and distinct whenever a part time was played, as was also when piano was performed its sounds became confused and indistinct. The fault lie in the arrangement of the transmitters at Siemens's; they were fastened to the entrance of the pavilion under which the band was playing. If they had been suspended

[illegible]

of the room, as was [illegible] done the [illegible] ition the effect would doubtless have been better. The two other telephone rooms are located by the Vienna Private Telegraph Company. A lady singing at Baden (about twelve miles from Vienna) was accompanied by a man playing the zither at Kornneuburg, about the same distance from Vienna, but on the opposite side of the Danube. The receiver itself was very successful, but the peculiar crackling noise of induction was only too audible and greatly interfered with the performance. In the third room was heard the finale of the first act of Verdi's "Aida," which was being performed at the Imperial Opera. The reproduction was perfect anyone, and the orchestra, the instrumental music and also the applause of the audience were reproduced with the greatest clearness. The Vienna Private Telegraph Company also transmitter almost identical with Berliner's, the only difference being that it has three parallel carbon contacts instead of one.

ELECTRIC RAILWAY CARS.

There is an apparatus, not quite new, called the Hallmark-Wilmhill locomotive lamp for illuminating railway trains. It would appear that the unavoidable vibration and frequent shocks to which a railway train is exposed would render the gas lamp wholly unfit for illuminating purposes. The lamp successfully overcomes this difficulty, and is used on the Kronprinz Rudolf Bahn, in Austria. It consists of two vertical tubes of different diameter and connected at the bottom; two pieces carrying the cotton serve in these tubes, which are filled with glycerine. At the bottom of one of the tubes is a small, hollow plug, connected with a lever, which terminates in an armature opposed to an electro-magnet. As soon as the current passes, the arm of the lever is attracted, the electro-magnet is instantly energized and attracts the lever. The piston closes the communication between the two tubes, causes a slight lowering of the liquid in one of the tubes, and consequently a withdrawal of the layer carbon, and the electric arc is formed. As soon for incandescence headlights, the lamp is attached to the front of the smoke box, and a small Schuckert dynamo placed in front of the bottom of the latter feeds the lamp. Such a lamp illuminates a space of about one-third of a mile and is very useful for lighting up a tunnel and for distinguishing signals.

Crewe, March 1884.

THE PROGRESS OF ELECTRIC LIGHTING.

A paper on this subject was read before the Society of Arts on March 5 by Mr. W. H. Preece, F.R.S., Mr. Fredefield, Abel, C.B., Crompton, and amongst others present were Mr. Hammond, Mr. Crompton, and a large number of gentlemen connected with electric lighting. Mr. Preece, in commencing his lecture, remarked that experiments had been made in some quarters to the effect that electric lighting was at present a failure. He proposed to show that this was incorrect, and that electric lighting was a most pronounced success. Electric company mongering and floating had, however, in many cases resulted in disastrous failure. Mr. Preece next pointed out that the effect of the Electric Lighting Act, introduced in 1882, the object of which was to prevent the formation of a monopoly such as that of water and gas, had been to add considerably to the obstacles in the way of progress, and stated that the act was all in the interests of one class, viz. the local authority. The lecturer next made a rapid survey of the extent to which electric light up to now enabled us to solve the problem of the economical supply of electricity. With regard to the claims of motive power in connection with the modern system for generating the electric current, water power, steam power, or gas engines had been employed. The latter he thought best, but were very imperfect in their workings. Recent improvements had been made in the manufacture of gas engines by increasing the quantity and quality of the iron, and by rearranging some parts of the machine, by which means it had been successful in doubling the output of one horse-power. Mr. Crompton had also produced a dynamo which would light up 250 lamps instead of 90, and Sir William Thomson had turned out a little machine capable of lighting 1,000 lamps by a mass of metal which one man could would not have sufficed for 100 lamps. With regard to alleged frequent breakdown of electric lighting, the lecturer had not examined one single case of a failure of an electric light that had not been traceable either to crass ignorance or to absurd attempts at economy. A sensation crusade was now being carried on against overhead wires. If properly constructed, these were highly desirable, and were especially adapted to electric lighting. In many instances they were, however, recklessly run up without method or system, and wanted. In the production of arc lamps two or three distinct makers had been obtained, and the working parts had been much simplified. For domestic illumination the glow lamp was eminently adapted. It was of no use to ignore the fact that there was a certain amount of danger in the introduction of the electric light into our homes; but careful rules and regulations had been drawn up for the guidance of those in charge of installations, and it was merely easy to employ sure but skilful and perfected contractors, and to leave the premises inspected periodically by the engineer to secure such guidance and safety as the electric light was capable of. Its harmless and devoid of danger. The accumulator was the next point that was the cause of numerous accidents by burns, fire, and explosion. The true solution of isolated house lighting, Mr. Preece thought, would be secured until we had obtained a reliable, effectual, and economical secondary battery. Plantè's original accumulator, as improved by Faure, Sellon, and Volckmar, had a progress towards this consideration steady progress, as exceedingly battery had the advantage that electricity could be stored up for use as wanted by day or night without the constant use of machinery. With regard to street lighting, the public, owing to the dazzling glare of the arc light, were not satisfied with the electric light of the same illuminating power as gas. A very interesting series of experiments was being conducted at Wimbledon to determine the best form of diffuser for use with the Siemens arc lamp. Herring referred to the electric light growing into favour with theatre managers, the lecturer remarked that the Marquis of Salisbury—himself an amateur electrician of no mean type—had established a system at his seat at Hatfield. Our New Law Courts were admirably lighted, and some of the judges had said that the electric light was the only good thing in the Palace of Justice. The electric light had been adopted in numerous hotels, public buildings, and railway stations; but its introduction was especially desirable in our homes, inasmuch as by its use there was no air vitiated, and a smaller amount of heat was produced than by gas, oil, or candle. Then the electric light was the purest and the most healthy. With regard to primary batteries, Mr. Preece remarked that these, owing to their cost, had not met with marked success. Railway trains on the Brighton and other lines were being admirably lighted by dynamos and secondary batteries. The energy of the moving train itself was capable of producing the current of electricity to illuminate every compartment with the light of day. It was difficult to ignore an epidemic as to the economy of electric lighting. In comparison with gas was not fair, as no central electric lighting station of sufficient magnitude at present existed, but the cost of supplying electricity now was far less than was the cost of supplying gas in the early days of its introduction. The public would have the electric light, however, not because it was cheap, but because it was safe, healthy, pure, soft, and natural; whilst gas was most insanitary and unhealthy. Questions of sanitation, ventilation, and decoration would determine the use of electricity, and not questions of price. At present it was a luxury for which we must pay; but such rapid progress was being made that it was evident the day was not far distant when we should cease to look on it as a luxury, but should demand it as a necessity.

In the discussion which followed, Mr. Crompton said that there was no reason for the impression abroad that electric lighting required more care than gas. As a manufacturer, his experience had been that the cost of production was steadily decreasing. What was wanted now was the practical breaking out of all that had been invented. Up to the present time had been there forward and systems had been neglected.

Mr. Gordon Salomons described an improved system of lighting by means of secondary batteries being carried out in Colchester, at present the only instance of a public system being carried out under the provisions of the Electric Lighting Act.

Mr. Hammond thought that the bar to quicker progress had been bad workmanship, and the determined opposition of gigantic capitalists connected with the gas interest.

Mr. Taylor Smith exhibited numerous portable incandescent lamps, which by means of a shoe and socket fixed in the wall could be removed from one position to another. Also candelabra capable of being raised or lowered as required, and other contrivances.

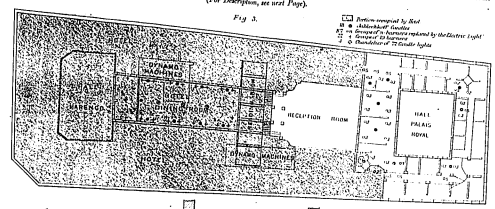
In moving a vote of thanks to the lecturer, Sir Frederick Abel expressed the hope that, as the use of gas rapidly extended in new directions not previously contemplated, we should see electricity gradually supplant it as an illuminating agent.

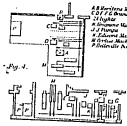
Mr. Preece made a few remarks in reply.

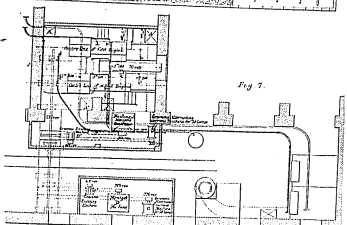
THE ELECTRIC LIGHT INSTALLATION OF THE MAGASINS DU LOUVRE.

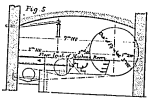
(For Description, see next Page).

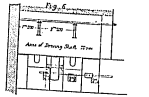
Fig. 3.

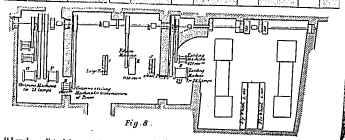












by having her nets cut, which saved her from a torpedo, that would otherwise have probably sunk her. Our men were as cool as if they were only going to have practice at a target. They did everything ready, and the result shows what can be done with three boats, five out of seven torpedoes discharged, taking effect, and either sinking or disabling a ship of the enemy.

"I have now given you a full account of the Battle of Port Said, and there is little more to tell you; I hear that the Ocean, which was knocked all to pieces by the heavy guns of the Inflexible, went down during the night of the 2nd. We are anxiously waiting for news of the Channel Squadron; if they fall in with the enemy they will capture or sink every ship, but I fear that we shall not be able to hear anything for some days.

"I enclose a list of the enemy's ships with all the information we have yet been able to obtain:

COMBINED FLEET AFTER THE BATTLE.

French Fleet.

Amiral Duperré: Sunk by torpedo from boat of Colbrook.
Devastation: Sunk; rammed.
Friedland: Sunk by torpedo; night attack.
Heroine: Serviceable.
Héros: Foundered during night of 2nd inst.; battered by heavy gales.
Redoutable: Serviceable.
Gilbert: Serviceable.
Suffren: Compartment filled by torpedo night attack.
Tolbert: Sunk by torpedo; night attack.
Surveillante: Sunk by torpedo, during battle.
Richlieu: Serviceable.
Ocksomoma: Sunk by torpedo; shortly after first charge.

Turkish Fleet.

Yeth-i-Bahrei: Compartment filled by torpedo; night attack.
Orchanieh: Sunk by torpedo from boat of Alexandra; early in battle.
Archer Shefket: Serviceable.
Assar-i-Tefik: Sunk by torpedo; shortly after first charge.
Intombeh: Serviceable.
Mendeelie Hedr: Sunk by torpedo; night attack.
Avini Illah: Serviceable.
Four corvettes: Serviceable.
Merveille: Sunk by ram.
Twenty-six torpedo boats: Seventeen destroyed.

Total Loss.

Ten ironclads sunk, one torpedo-ship, seventeen torpedo boats.

Existing Fleet.

Nine ironclads, four corvettes, nine torpedo boats."

This account, written by Lieutenant Forrest, will

THE NATIONAL ELECTRICAL CONVENTION.—The six days' work of the Electrical Exhibition has terminated very satisfactorily, considering the many disadvantages under which it has laboured. Of these, one of the most serious was the intense heat of the valley—a drawback which will doubtless be avoided in the case of any future appointments. It is to be regretted that on this occasion, in which the respective advantages of theory and of practice in the electrical field have been brought together for the first time, further encouragement affording no opportunity for discussion, there should have been any apparent disposition to depreciate the value of the theoretical researches of those who have revolutionized their knowledge. Even in connection with the dynamo machine, the telephone, the telegraph, and many others of such a feeling existed, the of all others was the occasion on which to harp it. It is difficult to realise that in the scientific investigation of electricity, where practical results are brought about by every attempts, it should be asserted that no person has a right to theoretical opinion on any of its theoretical problems "without a knowledge of its mathematics." Such a dictum would have suppressed the investigations of Faraday, and rendered it impossible even to power the researches of Clerk Maxwell. Science is work for all, and none of us are so wise but that we may gather some grain of knowledge from many to whom the higher mathematics are a sealed book. The indispensable value of purely scientific investigation is fully recognised by all, but it has not fallen to the lot of every one of those who are blessed with minds to conceive and hands to execute, to be supplied with elaborate apparatus and ample resources with which to demonstrate that a certain theory must be correct, and that a certain result must follow. Sir; this is a free country, and we live in the nineteenth century, and this particular period even the importance of the lesson which it teaches is generally recognised. One of the most significant results of the conference was the apparent disappearance of this feeling, as the arena of discussion gradually developed the fact that the experience of practical men was, after all, as interesting and instructive as that of the theoretical student. This was due, in a great measure, to the introduction of a considerable foreign element, which has been trained in a school where theoretical knowledge has been brought into closer relationship. The work which has been done auspiciously inaugurated should now be taken up by individuals and associations, in order that it may be perpetuated by the same enthusiasm which—*The Electrician and Electrical Engineer.*

June—Sept. 5, 1882.

ELECTRIC LIGHTING FOR RAILWAY TRAINS.—We hear so much of the progress of electric lighting in America, and are assured so often that in England we are, so to speak, in the dark in this matter, that we may be allowed to wonder how the terrible accidents reported from Greely, Colorado, should have been possible. A train, having one, taking sixty men of a circus company to the sleeping-trucks, caught fire. There were twenty barrels of gasoline on the car; these were set on fire, we are told, either by sparks from the engine or "by the torch used to light the room to bed." Nine of the sleeping men were burnt to death, and two others badly injured. Surely this could in event with attention be entirely prevented. Sleeping railway carriages, whether they be sleeping-cars or not, are lighted electricity, both in the United States and here at home.—*Leeds Mercury.*

June—Oct. 7, 1882.

THE ELECTRIC LIGHT ON BOARD HER "COLOSSUS."—A satisfactory trial is reported to have been made last week of the electric lighting apparatus on board the *Colossus* at Chatham. This is the most comprehensive installation which has yet been introduced on board an English ship of war, the whole vessel being lighted by electricity. In addition to the complete lighting of the ship herself, the dockyard by a connection with the installation includes the lighting of three powerful searchlights, as well as incandescent yard-arm lights. The system adopted is that of the Anglo-American Brush Company. The interior of the ship is lighted by 100 lights of 20 and 100 lights of 10 candle-power, the lamps being also manufactured by the Brush Company. The current is produced by three Victoria dynamos, coupled to Brotherhood engines. The test consisted in running the machinery for six hours continuously, with a full load of 180 amperes and an electro-motive force equal to 80 volts. The dynamos rotated at the rate of 400 revolutions a minute, with 40 lb. pressure of steam.

AN ELECTRIC LIGHTHOUSE IN BRAZIL.

An electric lighthouse has recently been erected on the island of Itaca, at the entrance of the Bay of Rio Janeiro. The lighthouse proper is 85 feet high, and is put upon a rock 230 feet in height, so that the focus of the light of the apparatus is fixed at an elevation of 315 feet above the sea. The electric current is produced by a continuous current Gramme machine, working at the rate of 700 revolutions, and feeding a light of 2,000 candle-power. The Gramme machine referred to is worked by a stationary surface-condensing steam engine; this arrangement being inevitable owing to the want of fresh water. All the fittings are double, so as to prevent interruptions by unforeseen accidents; and, to make assurance doubly sure, an oil lamp is always kept in readiness. The light is revolving, having two white discs and one red one, succeeding one another at fifteen minutes' interval, and the light is visible at a distance of about 35 statute miles.

June—Sept. 12, 1882.

THE ELECTRIC LIGHT ON BOARD SHIP.—The *Rapid* made a successful trial of her electric illumination on September 4. She has 101 32-candle-power lights, and 200 of 10 candle-power, as well as sixteen 50 candle-power searching lights. The whole is driven by one of Allen & Nelson-Hopkinson dynamos, driven by one of Joyce's "Invincible" compound engines. The engine was being driven to 465 revolutions a minute, whereas the maximum allowed by the contract, is 500.

ELECTRIC LIGHTING FOR RAILWAY TRAINS.

Powerful electric lights have become exceedingly important as regards the safety of life and property at sea, while vie with each other in the development of apparatus suited to their special needs.

Enormous increase in the power of single lights has been obtained during the past few years by the great improvements which have attended the introduction of electricity as an illuminating agent. This has benefitted the defence more than the attack, whether the operations be on land or sea; for, usually, the main functions of a powerful light are to guard against surprise, to give the defender a timely warning, and to enable those to aim at the advancing forces. The defence can, moreover, employ the most powerful lights, the machinery for which is sometimes more than suited to the mobility required by the attack. Nevertheless the use of a powerful light may frequently aid the attacking forces very materially. Thus, during the attack on Charleston during the War of Secession, the Southerners were prevented from repairing the breach in Fort Sumpter by night on account of a deadly glimpsed fire which was directed upon the breach by the aid of a limelight, which is so inferior to the light now obtainable by means of the electric arc.

Again, in an advance over obstacles it has been found that the attacking party will often receive great assistance from the electric lights of the defence. As before stated, however, the balance of advantage appears to be considerably on the side of the defenders.

In all descriptions of siege operations the employment of the electric light has become a matter of considerable importance, many operations which it has hitherto been customary to perform under the cover of darkness being no longer possible, and other operations, such as the bridging of rivers, which formerly could only be carried on during daylight, being now possible on the darkest night.

But the two important war services for which powerful electric lights have been provided, in this country, are:

1. As search lights for the vessels of our Royal Navy.

2. As search lights to act in unison with the artillery and submarine mining defences of our ports and harbours.

In the one case the machinery is carried on board our large men-of-war, and in the other case is erected inside our forts. In each of these positions the machinery can be placed practically out of reach of an enemy's shot and shell; but the protection of the projector, and of the men who manipulate it, can never be so satisfactorily provided for, and the subject has consequently received a good deal of attention, both in the Army and Navy. The subject has especially been worked up by our Royal Engineers, and has been attacked in two ways:

1. By attempts to place the projector and manipulators out of the direct line of an enemy, and to use a mirror for the final projection of the ray of light in his direction, such mirror being exposed to the fire, but being arranged so that it can be easily and quickly replaced.

2. By attempts to greatly decrease the cost of the projector, and to arrange the optical portions so that they can be expeditiously replaced if broken.

The projectors at first used both in this country and abroad were large metallic reflectors, either parabolic or hyperbolic, fixed on a lighter, smaller, and equally powerful arrangement was found in the Fresnel system of reflect a spherical holophote. It consists of a central lens, generally in three pieces, of a focal distance of 0.35 m., and which receives directly the light rays in a cone of about 60 deg. The catadioptric portion is composed of five or six annular rings so placed that the principal focus of each one coincides with that of the dioptric portion. There is also sometimes added a small spherical metallic mirror, placed behind the focus, so as to catch and throw forward again the rays from the back of the arc light. Owing to the short focal distance, it is very difficult to focus the light properly in these costly projectors, and the glass rings are frequently cracked by the flame and heat from the electric arc. For short ranges, however, they are efficient.

These projectors have given place to a most effective arrangement designed by Colonel Mangin, of the Corps du Génie (French army), and which consists of a reflecting iron ground on the inner side to a spherical surface of somewhat shorter radius than the outer spherical surface, the glass of the reflector being, therefore, thicker at the sides than at the centre. In fact, the projector is a spherical catoptric apparatus, the divergence of which is rectified dioptrically.

The perfection of the arrangement will best be shown by comparing Mangin projectors by Messrs. Stuttzer, Lemonnier, et Cie., the sole manufacturers.

TABLE SHOWING THE DIMENSIONS AND THE DIAMETERS OF THE LIGHTS OBTAINED AT DIFFERENT DISTANCES WITH VARIOUS MANGIN PROJECTORS.

	0.800	7	115	230	345	460			

Fig. 1, on the following page, shows one of the 0.90 m. projectors complete, with the inclined hand lamp, screw in bottom of the head for focussing, sup-bolts on side for observing the carbon points—an image of the arc being thrown, by means of a small lens, upon a piece of ground glass. The hood is mounted on a stand wholly a motion in altitude and azimuth can be obtained, and the whole is carried on a spring wagon or they fitted with all the necessary tools.

By means of an inclined lamp nearly 90 per cent. of the total light can be thrown towards the mirror, a constant current being employed, and the mechanical details of the feed arranged accordingly.

Fig. 2 represents a smaller Mangin projector of 0.60 m. diameter, and which also figures in a few of the mechanical details. It is fitted with two hand bars, and can then be moved about by two men, the lattice-work stand being screwed to the ground when these projectors are used, and to place them so as to look over the parapets of our forts or the bulwarks of our ships is to invite their speedy destruction by an enemy's fire.

To meet this difficulty arrangements were made and tried at Chatham in accordance with suggestions made by Major Sale, R.E., C.M.G., in 1876-7 then Secretary R. E. Committee, to place the projector on a platform-carriage, and direct the beam of light on to a plane mirror placed a short distance of and above a parapet to the enemy's fire. The results were encouraging, but difficulties were encountered in the fixing and manipulation of the mirrors, the apparatus tried being so weak that the wind moved the mirror unduly.

In these designs the projector and the mirror or mirrors were placed nearly in the same horizontal plane, and there was a loss of light when the mirrors were approaching at extreme angles of training. Moreover, the range was limited, and unless large mirrors were used (in some situations not convenient, and which does not possible) no appreciable effect is had, the portion of the whole circle illuminated was limited. And in some situations the length of parapet required could not be spared.

In April, 1880, Lieutenant Mangin, R.E., proposed the following arrangement:

1. To work the ray of light to the zenith, either directly or by means of a mirror.

2. To deflect this ray by an upper mirror carried in a framework or funnel.

3. To carry the funnel or tube that supports the upper mirror, upon a ring, and this again upon another and another till it is finally stayed to the inner wall or walls of a fort. A slow motion screw, a worm, &c., would then move the funnel in azimuth at pleasure, and consequently the ray of light from the mirror.

4. To move the upper mirror by a slow motion screw actuated by a light grip wheel on the axis of such screw, which wheel can be turned by an endless cord from below, by a man who would take his orders through a speaking tube from an observer in the firing station. The only commands required would be "up, down, right, left, fast, slow."

Such a tube could be taken down at daybreak and put up again in the evening in a few seconds by a telescopic arrangement like that used in raising and lowering Thames steamboat funnels. It is difficult to work a light ray direct to the zenith, especially

with a "Mangin" projector, as the burst pieces of hot carbon fall on the glass of the projector at the thinnest part (the centre) and perforce crack it. The vertical ray can, however, be readily obtained by means of a lower mirror.

It should be noted that this arrangement provides for reflection at about 45 deg., a very small angular movement of the upper plane mirror producing a large vertical motion of the ray of light.

Fig. 3 (page 409) represents such an arrangement which consists of a wrought-iron tubular structure 20 ft. long and 30½ 3in. in diameter made of boiler

THE ELECTRIC LIGHT IN LONDON.

We are as yet very far from a general application of electricity for the lighting of the streets of London, although, so far as legislation was concerned, that boon appeared to be secured for the metropolis. We learn that the Board of Trade have decided to proceed at once to revoke no fewer than twenty-five of the provisional orders which were granted by them last year, and subsequently confirmed by the Parliament, for the electric lighting of London and its suburbs. Of this number, twenty-three are orders which were obtained by the Metropolitan Brush Electric Light Company, which has since gone into liquidation. These orders relate to the electric lighting of Barnes, Mortlake, Bermondsey, Chelsea, Chiswick, Clerkenwell, Finchley, Greenwich, Hackney, Holborn, Hornsey, Islington, Limehouse, Poplar, Rotherhithe, St. George's-in-the-East, St. George the Martyr, portions of the parish of St. Giles, the parishes of St. Luke's, St. Olave's, St. Saviour's, Southwark, Shoreditch, Whitechapel, and an order known as the Wandsworth order, which, however, relates to portions only of the parish of Clapham. Of the other two orders which will be revoked, one relates to the lighting of Kensington, and the other is an order granted to the Pilsen-Joel Electric Lighting Company, with powers to light those portions of the parish of St. Giles not granted to the Metropolitan Brush Company. So far as London is concerned, the result, therefore, of the numerous electric lighting orders which have been granted during the past two years is that only eight now remain in force, namely, the St. James's and St. Martin's orders, which, with the Hanover Square, Strand, and Victoria district orders, are now held by the Edison and Swan United Electric Lighting Company; the Hampstead order, granted to the Hampstead Electric Lighting Company; the St. Pancras order, granted to the twenty; the order for the lighting of Fulham, which was granted only last May to the West Middlesex Electric Lighting Company; and the order, also granted in May last, to the West London Electric Lighting Company, for lighting portions of the parishes of St. George's, Hanover Square, St. James's, Westminster, and St. Martin-in-the-Fields. Of these eight orders, the first five have already had their time extended within which to comply with the provisions of the orders, and unless these provisions are complied with before October 15 next, the powers will be lost unless a further extension of time is granted. With those facts before them, the metropolitan public, it appears to us, will come to the conclusion that electric lighting is still in its infancy, and that great improvements, combined with a reduction of the charges made for the electric light, are impending. Londoners, moreover, will be satisfied for the present with gas, not in the least concerned whether electric light companies are ruined or not.

ELECTRIC LIGHTING.

TO THE EDITOR OF THE "STATIST."

SIR,—In your last issue, in an article upon "Electric Lighting in America," you refer to the installation by this Company at Colchester. I shall feel obliged by your allowing me to point out that the system adopted at Colchester is so entirely different from that of the Edison Company, that it is misleading to draw any inference from the results of the installation in America as to the working of this Company's system. At Colchester the lighting is entirely from storage batteries, placed in five centres in different parts of the district, which are charged in series from a central station where the electricity is generated. The street works, in which cables have been laid for supply of 2,200 lamps of twenty-candle power, the steam power, dynamo-machines, accumulators, the fitting of the stations, and every appliance for complete working of 2,200 lamps, under the provisions of the licence from the Board of Trade, will not exceed £11,000. The annual working expenditure, including fuel, wages, rent, &c., and 10 per cent. depreciation, will not exceed £1,100, and a much larger business could be carried on with very little additional expense beyond cost of fuel, &c. If you compare these figures with your statement that the cost of Edison's station was over £200,000, and the working expenses £16,000 (you do not say if this includes depreciation), for the supply of 12,540 lamps, you will find that a similar plant upon our system, put down in this country, would have cost only £52,700, and the working expenses also proportionately less. This Company recently estimated for an installation of 5,500 lamps on the Colchester system, and the cost of steam-engines and boilers, dynamo-machines, secondary batteries, charging and distributing cables, and service wire, and all the electrical apparatus, amounted to £32,050; whereas the same installation upon the direct system was estimated at £51,000, the great difference being in cost of conductors. The lighting at Colchester is entirely from secondary batteries, which are charged during the day, and are never used in combination with the dynamo-machines. The system is fully described in the enclosed paper, read by our engineer on the occasion of the installation at Colchester being inaugurated on June 11th last. So far from the experiment at Colchester being a permanent loss to the Company, it will leave a large margin of profit as soon as the 2,200 lamps are installed for which the cables have been laid; but the installation is growing in having practically demonstrated the success of the first attempt to supply house-to-house lighting from storage batteries in central stations. The works have been visited by many British and foreign electrical engineers, with the gratifying result that the system has already been adopted for house-to-house lighting in an important Continental city, the first shipment of plant having been made by this Company last week.—I am, Sir, &c.,

GEO. OTTON,

Manager, South-Eastern ("Brush") Electric Light and Power Company (Limited and Restricted).

68A *Cowcross Street, London, November* 20th.

THE ELECTRIC LIGHT IN THE MAGASINS DU LOUVRE.

(Concluded from page 48.)

In our previous article we gave a description of the electric light installation as it actually exists at the Magasins du Louvre. We explained that this installation, very carefully arranged in a practical point of view, is directed with great care, and that a very detailed account is kept of the expenditure involved. The figures we shall now give, and which we owe to the kindness of M. ——, are therefore absolutely exact; they are deduced from a careful examination of the official accounts, and refer to the year 1882, during which the electric lighting of the Louvre was carried on without unusual complications, without any change or interruption.

As we stated in the previous article, the lighting of the Magasins is effected by five Gramme machines with independent exciters; each of these supply eight circuits of three Jablochkoff candles, or 120 in all. There are also two Merrison machines, each of five circuits, feeding thirty candles in all, or a total of 460; there are, besides, four other dynamos, each working an arc lamp, and one Edison machine, type 'A,' supplying sixty incandescence lamps.

The expenses relative to this installation have been separated from the general accounts, and include the following items:—These are as follows:

1. Those of first cost.
2. The annual interest on cost of the lamps.
3. The cost of maintenance and working.

In any ordinary installation the first costs are generally easy to arrive at; the second are usually calculated more or less approximately; the expenses of the third it is rarely that running and maintenance are carried on with sufficient accuracy: these, however, are the most important of all.

During 1882 the Jablochkoff candles in many of which it will be remembered during this year 4 candles were set at night, gave a total of 294,978 hours; the four arc-lamps furnished 1,736 hours, or a total of 296,714 hours; as they are each equivalent to five candles power, the total for an uninterrupted work is represented, their proportional port corresponds to 2962 × 5=14,710 hours. The sixty Edison lamps were recently placed, furnished during the months of November and December last, 2,000 hours of light, but each of them absorbed only 0.2 of the power taken by a candle, so that their proportion of power absorbed was 0.2 × 20,205=4241 hours. We have thus a total of 221,570 hours of light, of equal intensity. The foregoing is the basis from which the calculation of expenses, management, fuel, stores, &c., has been arrived at for each of the different systems.

The 201,578 hours of lighting supplied by the Jablochkoff candles, corresponds to a total of 130,246 candles consumed; hence the average duration of each candle was about 1.5 hours. The part of the expenditure works out, at the price at which the candles are supplied to the Magasins du Louvre, to, 121 francs (1.19) per hour; the cost of working and maintenance corresponds exactly with the same figure; as to the allowance for loss and depreciation of the candles, we have put an amortisation of all the capital invested in the installation—for candlers, steam power, material of all kinds, conductors, lamp brackets, &c.—it corresponds to a total of 0.145 francs (1.36d.).

The whole of the expenditure per candle amounts, 0.393 fr. (3.79d.) per hour, divided as follows:

	francs.
Candles	0.121
Motive power and maintenance	0.121
Sinking fund and interest	0.145
Total	0.393 (3.79d.)

The cost of the arc lamps is made up as follows:

	francs.
1. Of the carbons consumed, which divided by the 2922 hours of lighting, cost per hour	0.221
2. Of the maintenance as before	0.030
3. Of amortisation charges	1.001
Total	1.812 (17.46d.)

Lastly, the account for the Edison lamps stands as follows, allowing a service of 800 hours per lamp:

	francs.
First cost 7.5 fr. (6s.)	0.0094
Maintenance	0.0094
Amortisation	0.0188
Total	0.0376 (.36d.)

It should be observed here that the general expenses connected with the production of motive power are, in the original accounts, grouped together, and that the distribution made has been arranged proportionately among the different systems, which the expenses special to each system, are in all cases kept separate.

An observation should here be made on the hourly consumption of the Jablochkoff candles. Until the year 1883 the lighting of the candles was carried out in multiple thresholden at the Magasins du Louvre, and with hand commutators manipulated by an attendant, when it was necessary to substitute a new candle for one that was burning out. In consequence of this, in order to avoid extinction, it was necessary to be always a little in advance, and consequently to sacrifice a certain amount of the candle which was not burnt. Moreover, when the candles in the first chandeliers of a circuit were lighted simultaneously, it was necessary to regulate the change either by the candle which first burnt the quickest, or by the shortest one of the group. From this it followed that some of the candles were entirely consumed, and a considerable waste was entailed. The suppression of this loss was a problem which long occupied the attention of those using the Jablochkoff candle, and many special devices have been advanced for the automatic lighting of the candles. Unfortunately all these arrangements, more or less complicated, have failed to answer in practice, although great ingenuity has been exercised on the subject. At the Magasins du Louvre, the practical management of the electric lighting is placed, under the superior direction of M. Hospitalier, in the hands of a chief electrician, M. Cherbit, for a long time in the employment of the Jablochkoff Company. This gentleman has carried out, as the result of a very original and very practical, by which, at an increased cost of candling less than one centime per candle, the relighting can be effected automatically and without any failure, and to secure an economy of 20 per cent. on the consumption of the candles, by avoiding the constant use of unburnt ends of candles. This arrangement of M. Cherbit, the description of which we reserve for the present, thus prevents large loses without any delicate manipulation, and with a certainty that has never failed. Thus modified, the cost of the Jablochkoff candle per hour is:

	francs.
Candle	.101
Maintenance	.122
Sinking fund	.149
	.372

In order to afford a means of calculating in what proportion the various systems of electric lighting which have replaced gas, are more economical than the latter, we may add that the Magasins du Louvre pay at present for gas .36 francs per cubic metre (6s. 9d. per 1000 ft.), which is equivalent to a cost of .054 francs per burner of 140 litres per hour (5 cubic ft.). The maintenance would come to .005 francs and the amortisation of the installation, calculated on the same basis as for electricity, to .014, or a total of .073 francs (.68d.) per hour and per burner of 6 fr. of gas. The total cost of gas lighting is thus raised to about 8c. 6d. per 1000 cubic feet. We have already seen in the previous article that there has been established at the Louvre, one Edison lamp for *one* gas burner of 6 fr., and one Jablochkoff candle for *about ten* such burners; while more lately *five candles in one cluster have replaced a Jablochkoff candle.*

Consequently, if we compare the cost of lighting by each system, with the light furnished by one cubic metre (35.3 ft.) of gas, we shall have the following values:

	francs.
Cost of gas per metre	.201
Edison lamps	.206
Jablochkoff candles without the Cherbit arrangement	.316
Jablochkoff candles with the Cherbit arrangement	.260

* Photometrically, *two* Jablochkoff candles appear to be necessary to give the light of a gas burner; actually, however, more very closely to *one* burner is given, because of the fact that the Jablochkoff candle is lighted on account of the greater facilities for distributing the light.

Advertisements intended for insertion in the current week's issue of ENGINEERING must reach the Publishing Office not later than five o'clock in the afternoon of the previous Friday. Small Advertisements will be inserted at the following rates, viz.:—Not exceeding four lines, 2s. 6d.; and 6d. per line for every additional line. Terms strictly cash. Postage stamps received in payment. Small Advertisements will be inserted with all privileges in the Weekly Edition, which has a large circulation.

SUBSCRIPTIONS, HOME AND FOREIGN.

The price of ENGINEERING is 6d. per number. Subscribers in the United Kingdom remitting 26s. 6d. for six months, or 53s. for twelve months, if such be taken, the address is 2s. 6d. extra, the subscription is 28s. 6d. for six months, or 57s. for twelve months. Subscribers in India and China, for whom copies are sent through the Overland Mail, are charged £2 for six months, or £4 for twelve months, which sum must be remitted in advance. Subscribers in the Australian Colonies, for whom copies are sent viâ Brindisi, are charged £2 10s. for six months, or £5 for twelve months, which sum must be remitted in advance. Subscribers in the United States, for whom copies are sent viâ Queenstown, are charged 28s. for six months, or 56s. for twelve months, which sum must be remitted in advance. Subscribers in France, Belgium, Germany, Italy, Spain, Portugal, Switzerland, Russia, Sweden, Norway, Denmark, Holland, Egypt, Malta, Mauritius, Cape Colony, Natal, Queensland, New Zealand, Tasmania, Victoria, Japan, Java, Singapore, Straits Settlements, Mexico, Brazil, Chili, Peru, Uruguay, Argentine Republic, Canada, Spain, Austria, Hungary, Belgium, Brazil, Bulgaria, Chili, Constantinople, Egypt, Finland, Greece, Holland, Java, Mexico, Peru, Portugal, Roumania, Russia, Servia, Spain, Switzerland, Turkey, Uruguay, Venezuela, Zanzibar, and the Transvaal, are charged 28s. for six months, or 56s. for twelve months, which sum must be remitted in advance. Subscribers in Germany, Austria, Belgium, Brazil, Bulgaria, Chili, Constantinople, Egypt, Finland, Greece, Holland, Java, Mexico, Peru, Portugal, Roumania, Russia, Servia, Spain, Switzerland, Turkey, Uruguay, Venezuela, Zanzibar, and the Transvaal, are charged 28s. for six months, or 56s. for twelve months, which sum must be remitted in advance. Subscribers in France, Belgium, Germany, Italy, Spain, Portugal, Switzerland, Russia, Sweden, Norway, Denmark, Holland, Egypt, Malta, Mauritius, Cape Colony, Natal, Queensland, New Zealand, Tasmania, Victoria, Japan, Java, Singapore, Straits Settlements, Mexico, Brazil, Chili, Peru, Uruguay, Argentine Republic, Canada, Spain, Austria, Hungary, Belgium, Brazil, Bulgaria, Chili, Constantinople, Egypt, Finland, Greece, Holland, Java, Mexico, Peru, Portugal, Roumania, Russia, Servia, Spain, Switzerland, Turkey, Uruguay, Venezuela, Zanzibar, and the Transvaal, are charged 28s. for six months, or 56s. for twelve months, which sum must be remitted in advance.

Subscriptions for subscriptions to ENGINEERING from abroad are received by the following agencies, viz.:—Paris, Asher, Hayerey, Brion, Dumaine, Rue Bonaparte; Berlin, Asher and Co., 5, Unter den Linden; Vienna, Lehmann and Wentzel, Rothenthurmstrasse.

Subscriptions to ENGINEERING can commence at any time, and will be forwarded to any part of the world, post free, at the following rates:—Six months, 26s. 6d.; twelve months, 53s. Subscribers in the United States, Canada, and Australia, 28s. for six months, or 56s. for twelve months. Subscribers in India and China, £2 for six months, or £4 for twelve months. Subscribers in France, Belgium, Germany, Italy, Spain, Portugal, Switzerland, Russia, Sweden, Norway, Denmark, Holland, Egypt, Malta, Mauritius, Cape Colony, Natal, Queensland, New Zealand, Tasmania, Victoria, Japan, Java, Singapore, Straits Settlements, Mexico, Brazil, Chili, Peru, Uruguay, Argentine Republic, Canada, Spain, Austria, Hungary, Belgium, Brazil, Bulgaria, Chili, Constantinople, Egypt, Finland, Greece, Holland, Java, Mexico, Peru, Portugal, Roumania, Russia, Servia, Spain, Switzerland, Turkey, Uruguay, Venezuela, Zanzibar, and the Transvaal, £2 10s. for six months, or £5 for twelve months. Subscribers in Germany, Austria, Belgium, Brazil, Bulgaria, Chili, Constantinople, Egypt, Finland, Greece, Holland, Java, Mexico, Peru, Portugal, Roumania, Russia, Servia, Spain, Switzerland, Turkey, Uruguay, Venezuela, Zanzibar, and the Transvaal, £2 10s. for six months, or £5 for twelve months.

Orders for Publication and Advertisements, Nos. 20 and 26 Bedford-street, Strand, London.

TELEGRAPHIC ADDRESS—ENG. LONDON.

ENGINEERING is registered for transmission abroad.

BINDING CASES.—Binding cases for containing twenty-six numbers of ENGINEERING can be had of the Publisher at 2s. each.

NOTICE TO AMERICAN SUBSCRIBERS.

In accordance with an agreement we have negotiated Mr. Lucas Smith, of 55, Chancery Lane, London, W.C., to receive all moneys due to us in the United States. Mr. Lucas Smith's receipt for any moneys due to the Publisher will be a payment to him. Mr. Lucas Smith is also authorised to receive subscriptions for ENGINEERING, and will attend to all matters connected with the publication. The annual subscription for ENGINEERING, delivered in any part of the United States, is Five Dollars.

NOTICES TO CONTRIBUTORS.

The Publisher begs to state that he is able to supply one or two sets of Engineering Periodicals to Engineering Students at half-price.

The Publisher desires to direct the attention of Manufacturers and Purchasers to the advantages offered by a Series of Advertisements in ENGINEERING *now established at the Offices of the Publication, and forwarded regularly to the Chief Engineering Offices of the Railway and Steamship Companies, Engineering Contractors, Engineering Firms, Technical Journals, and the Libraries and Institutions of the United Kingdom, the Colonies, and Foreign Countries, thus ensuring wide distribution. A large number of the various Trade Circulars which appear either exclusively or from time to time in* ENGINEERING *are forwarded to Subscribers, which will be inclosed in Parcel Wrappers whenever desired.*

ENGINEERING.

FRIDAY, JANUARY 13, 1882.

THE ELECTRIC LIGHT AT GODALMING.

GODALMING, a small town of some 6000 inhabitants, standing upon the River Wey, and being about midway between London and Portsmouth, has been for some weeks past in the forefront of the contest of the electric light arena. In September the contract with the local gas company for the lighting of the town expired, and it was decided by the authorities not to renew it, but to give the electric light a chance of showing what it could do. Messrs. Muirhead and Barrett undertook to instal the electric light upon the understanding that the annual cost was to be less than the 200*l.* a year, which was the amount of the gas contract. It was thought that by utilising the water power afforded by the Wey, this result could easily be achieved, the expenses of the arcane being large and a bit of water five feet being generally available. An agreement was come to by Messrs. Calder and Barrett with Messrs. H. and J. Pulsan, leather dressers, who have exclusive rights at this point over the water power, which is used by them for driving their mills, to allow the water power to be used for the light, in consideration of having their own mill and premises lighted gratis. The remainder of this arrangement there are lighted and seven incandescent lamps are placed in their premises, whilst the town itself is illuminated by four arc lights and 27 incandescent. The arc lights are of 2000 candle power each, and are given by Messrs. Siemens Brothers' well-known type, the incandescent are Swan lamps which are capable of giving off 30-candle lights. The current is supplied by a Siemens alternating current machine, working at a speed of 850 revolutions per minute, the field magnets of which are excited by an ordinary Siemens shunt-wound machine, working at 1000 revolutions a minute, and giving off a current of 12 webers. The alternating machine is coupled up into two circuits, one circuit being devoted to the arc lights, and the other to the 34 Swan incandescent lights. The arc-light circuit has a current of 12 webers, and an electromotive force of 2600 volts, while the incandescent light circuit has a current of 25 webers and an electromotive force of 1000 volts. These two circuits are said to require 10 horse power to drive them.

It was at first thought that a single Pouzzolet half-inch cotton water wheel of about 12-ft. 6-in. diameter would be sufficient to drive the machines, but it proved quite unequal to the task, and another similar wheel was coupled up with it. Together the two wheels are, in ordinary times, when the full head of water is available, just about sufficient to drive the required power, but, unfortunately, when the river is swollen by rains, the capacity of the engine is not sufficient to carry off the water quickly enough, and the tail-water stream is thrown back on to the wheels previously fixed and used in Messrs. Pulsan's mills, and not sufficiently adapted to the purpose for which they were now required. It has become necessary to fall back upon the steam power, and for this purpose a semi-portable engine has been procured and is used as an auxiliary to the water power. The ordinary steam is worked up to a pressure of only some 25 lb., but in case of need it is equal to the whole work required.

The strength of the currents in the two circuits in all times observed by means of Siemens' electro-dynamometer, which is fixed in a convenient position, so that it may be seen by the driver of the engine. In this instrument the current passes through a fixed coil of thick wire, and thence through a surrounding single coil of wire suspended in two mercury cups, and in the axis of the single coil, round which it can turn. The upper end of this coil is attached to a light spiral spring, which can be twisted by a thumbscrew, so as to oppose the action of the current and reproduce what amounts to turn the suspended coil about its axis, by an amount of twist of the spring sufficient to bring the coil in a normal position, its plane being then at right angles to the plane of the fixed coil. The strength of the current is given by the magnitude of the couple, and is found by multiplying the square root of the angle through which the spiral spring is turned to bring the coil into its normal position, by a constant which is experimentally determined. It is the duty of the engine-driver to regulate the speed of the engine so that the pulsator attached to the suspended coil oscillates about its mean position. The engine in this case is thus used to control the eccentricities of the water power, the bulk of the power required being generally given by the steam.

The arc lamps are lights, which, as we have remarked, are on one circuit, seem to be almost all that can be desired in the way of steadiness and brilliancy. The four arc lights which are disposed in the town light up the main street very fairly, and the leading lines of the system of installation generally, and the principal thoroughfare, and to supplement the arc lights by the small Swan lamps for the dark corners and side alleys. This system might no doubt have been carried out more completely, and more economically, had it been carried out, despite the work, but unfortunately the arrangements used do not quite meet the necessities of the case. In the interior of one of the shops in Mr. Pulsan's house the Swan lamps are seen at their best, and the light obtained leaves nothing to be desired. In the byeways of the town, however, the Swan lamps, where upon needed, fail to do their duty, their dull and glow contrasting, in some cases, very unfavourably with a few gas lamps which are lit. A little additional current would bring out their full glow, but from some cause or other this was not available. The chief reason of the failure of the Swan lamps in the town is simply the distance at which the source of electricity is placed from the town and the consequent resistance of the conductor. The arrangement of this conductor is worthy of remark. We have said that the wires 35 lamps are on one circuit, but this is not strictly true, and we should rather say that each Swan lamp is on a distinct circuit. One pole of the Siemens machine is connected with the ground through a convenient gas-pipe. From the other pole the conductor is led, like the trunk of a tree, from which branch off some in various directions, and these branching off, and these again, and so on to the required extent. The conductor running from the trunk of a tree is not only in the distinction of its branches and twigs, but also in their thickness, graduated. So the diameters of the various branches being so proportioned as to bring to the pole a maximum effect, we will endeavour to give to each lamp, as far as possible, its fair share of the current. This is effected by itself a spiral copper wire suspended from the houses by ordinary telegraph insulators, which is, we believe, a somewhat novel feature, and cold of course to be employed with economy of low tension. Then arranged the conductor is a tree whose root is the pole of the Siemens machine, and which is otherwise completely insulated from the ground. If the conductor be connected with the ground at any point the circuit will be closed, the current circulating, of course, with the resistance of this point from the machine. It becomes easy to pass the lamps in the order of their distance, which are much nearer to the machine, get much more resistance and have much more brightness than those in the town half a mile off, notwithstanding that a considerable resistance is caused by the long branch which leads to the mill. This resistance is obtained by a series of coils of thick iron wire, through which the branch current passes. The necessity of interposing resistance increases in proportion to the nearness of the point at which the current is taken off to the source of electricity, seeing that of the most serious obstacles to the adoption of this system of lighting on any but a small scale, as one of which the waste involved by the resistance, but also from the impossibility in burning of the lamps unless the resistances are very accurately adjusted.

The Swan lamps are arranged in the same way as lamps-posts of the town. The post is made to serve as one pole, and is connected to one side of the socket into which the lamp slips, the other side of the socket being connected to the conductor wire. This arrangement is at once simple and efficacious.

It is only that the installation has not been carried out in a way which should insure success, that we have alluded to it. Instead of the cut-off-the-way place chosen, it would have been easy to erect the engine and dynamo in the small town, and so to have brought the source of electricity to the centre of the town. As it is, the electricity has to be conducted for a distance of about a mile and a half, and this is the chief reason why the Swan lamps are not more brilliant. Had the town been lighted by electricity, it would have been by the system of *parallel* instead of *series*, and this is the system which we have seen work well, and that in the distribution of its branches and twigs, but also in their thickness, graduated. So the diameters of the various branches being so proportioned as to bring to the pole a maximum effect, we will endeavour to give to each lamp, as far as possible, its fair share of the current. This is effected by itself a spiral copper wire suspended from the houses by ordinary telegraph insulators, which is, we believe, a somewhat novel feature, and cold of course to be employed with economy of low tension. Then arranged the conductor is a tree whose root is the pole of the Siemens machine, and which is otherwise completely insulated from the ground. If the conductor be connected with the ground at any point the circuit will be closed, the current circulating, of course, with the resistance of this point from the machine. It becomes easy to pass the lamps in the order of their distance, which are much nearer to the machine, get much more resistance and have much more brightness than those in the town half a mile off, notwithstanding that a considerable resistance is caused by the long branch which leads to the mill. This resistance is obtained by a series of coils of thick iron wire, through which the branch current passes. The necessity of interposing resistance increases in proportion to the nearness of the point at which the current is taken off to the source of electricity, seeing that of the most serious obstacles to the adoption of this system of lighting on any but a small scale, one of which is

THE ELECTRIC LIGHT IN IRONWORKS.

For industrial establishments are so well adapted for being lighted by electricity as large iron and steel works. Their floor spaces are usually extensive and open, and the operations carried on are such as require a fairly strong but diffused light. The most recent installation of incandescence that we have heard of is that just completed by the Maxim-Weston Electric Company, at the Cengarvern Iron and Steel Works, now incorporated with the New British Iron Company, an old-established South Staffordshire concern. The electric lighting has complicated by the two distinct installations of Weston are large. The installations are perfectly distinct one of the other, being driven by separate engines and dynamos, and the lamps of one installation alternate with those of the other, so that one installation may always be depended on to carry on the lighting of the works should the other be stopped by accident or otherwise. The two installations are both in nightly use, and we understand are giving every satisfaction. A large portion of the iron and steel works must necessarily continue in operation, both day and night, and in such cases the value of the electric light is much enhanced. In the present case two lamps are placed above each of the nine rolling mills, and the remainder in the forge and steelworks. With this arrangement the place is exceedingly well lighted, although, of course, for special purposes, as in the case of setting rolls, &c., a special torch or gaslight is needed near the work. In the manufacture of the iron, however, the company anticipate less waste, a larger production, and better results generally than can be obtained in a place imperfectly lighted. The buildings of ironworks must of necessity—on account of providing ventilation, &c.—be very open, and in rough weather gas jets are often extinguished or blown about to such an extent that but little light is obtained from them, with the consequence that accidents to the machinery—more or less serious—occur most frequently during the night. Again, workmen will not keep gas burners in order, and too often they are removed, or the end of the bracket is broken off and the gas lighted, with the result that an enormous quantity of gas is burnt. With a good light like that from electricity, a much better supervision of the operations in progress is obtainable, and such operations are consistently facilitated. Independently, therefore, of the comparison of relative direct cost, such as would appear in balance sheets, showing the working of gas as compared with electricity, there are many important considerations. But in the installation we refer to, it is anticipated that the cost will not be appreciably more than that of lighting by gas. The cost of attendance is reduced to a minimum, fourmen's as the slushing, the dynamos, and the engines driving them (which are at Tangye's vertical types of 10 nominal horsepower, and specially adapted for electric lighting), are placed in the blowing-engine house, where an engineman is constantly in attendance. Again, several of the lamps are assigned to each of four men, who are in constant attendance on the mill engines, and who have sufficient spare time to clean and keep them in order, and to replace the carbons as required. A small weekly allowance is made to these men, which repays them for the little extra trouble they have, and the cost in this respect is therefore small. The Weston dynamo in the present case, is, in each installation, driven at a speed of about 1,350 revolutions per minute, when supplying the eleven arc lamps and 400 incandescent lamps. The armature of the cable comprising each circuit (about half-a-mile) is 1 ohm when cold, and 1·3 ohms when hot, and the current passing through it is about 19 ampères, the lamps with such a current being estimated to be of about 1,400 candle-power each. The dynamos are driven by ordinary 5-inch leather belts from short lengths of shafting, on each of which are mounted special wrought-iron pulleys 22 inches and 30 inches diameter respectively, the larger ones taking 7-inch belts from the 48-inch flywheels of the Tangye's engines, which have cylinders 10 inches and 14½ inches diameter respectively by 10-inch stroke, and work with a steam pressure of only about 30 lb. per square inch, making about 150 revolutions per minute. Several ironworks are now lighted by electricity, but those of the New British Iron Company are, we believe, almost the first in the South Staffordshire district. The example there set will, we think, not be without speedy imitation, as the advantages gained are considerable.

GULCHER ELECTRIC LIGHT AND POWER COMPANY.—Mr. Daniel de Caster, as a recent meeting, explained that on September 29th, 1881, new directors were elected. The directors reported to the last-paid shareholders of the company, placing before them the exact position of affairs, and from a number of their proposals the shareholders duly received unlimited support, and by means of the money thus obtained the company had been brought round to a safe and sound basis. The capital was originally £100,000, but was made up to November 30th, at which date they owed £9,000 to debenture holders (the renewed authority to borrow having £10,000), and £91,000 to their shareholders. They had no other debt of which to make mention. He trusted the patents as of no value, but that did not appear to be regarded as of great value. The stock stood at 6 to 7 dollar paid, they nominally standing about £7,000 of the stock, and of which there about £2,000 a year. There was hope yet for the company. It had been decided to bring a suit for action against Mr. Cookes on the ground of misrepresentation. Mr. Reeves (who said he was the largest shareholder) moved an amendment, adjourning the meeting and appointing a committee of investigation. The chairman ruled that he would not grant a poll. He afterwards put the original motion adopting the report, which he declared carried, and subsequently the directors were re-elected.

GREAT WESTERN ELECTRIC LIGHT AND POWER COMPANY.—The fifth clause of the agreement submitted to the meeting sets out that the liquidators should, within 21 days after the receipt of the special resolution for winding-up the company, pay to the directors, out of the cash belonging to the company, a sum equal to 10s. either on the written personal undertaking of the directors to apply this sum in paying a dividend of 10s. a share in the shareholding in the company. In addition, each member of the company would be entitled to receive from the Brush Company, at any time within the next twelve months from the date of the conditional agreement, to allot to him three fully-paid £5 shares in the Brush Company for every 20 fully-paid shares in the company. The resolutions to this effect were then adopted by an overwhelming majority.

BRUSH MIDLAND ELECTRIC LIGHT AND POWER COMPANY (Limited and Reduced).—At the second meeting Mr. E. H. Nye presided, and after adopting the accounts, a special meeting was held immediately afterwards to consider a proposal that the company should sell all its assets to the Anglo-American Brush Company, the consideration being that the purchasing company should satisfy all the obligations of the selling company, each member of the latter being entitled to acquire from the Brush Company, at any time within the next twelve months from the date of the agreement, seven 27 shares of £2 10s. each in the Midland Company, and so in proportion for any greater or less number. The proposal was carried, and thereupon the winding-up the company voluntarily under the provisions of the Companies Acts.

MAXIM-WESTON ELECTRIC COMPANY.—At an extraordinary meeting the resolutions were confirmed for reducing the capital by £100,000 to £150,000 by the cancellation of 20,000 shares, being unrepresented by available assets; for further reducing the capital to £150,000 by reducing the nominal amount of all the shares from £7 to 10s. each, thereby leaving the nominal capital as £150,000; and for increasing the capital to £250,000 by the creation of 20,000 shares of £5 each. The chairman stated that within a comparatively short period a great demand had sprung up for the company's lighting and he believed they were now on the road to making a prosperous business. At an extraordinary meeting, called to consider a resolution for the fusion of the company with the new company, the chairman said that the company was unable to go on owing to the fact the shareholders not paying their calls. The object of the fusion were that the present company should pay the whole of the debts of the company, and after that give shares for shares of the Maxim-Weston Company to the shareholders of the Lancashire Company. The fusion was agreed to.

THE ELECTRIC LIGHT ON THE PLACE DU CARROUSEL.

The immense Place in Paris that extends from the Louvre to the ruins of the Palace of the Tuileries, and from the Quai de la Seine to the Rue de Rivoli, has been, until very recently, lighted only in such a way as to magnify the obscurity of the night rather than to relieve it. The illumination was made all the more conspicuous after the brilliant illumination of the Boulevards, and of the Place du Théâtre Français, which is close adjoining. The new Rue de Rivoli, after leaving the Place du Théâtre Français, with the lamps of the Avenue de l'Opéra light, is reached by the quays by traversing the Carrousel, the passage from the one to the other, a short time since, fell into almost complete obscurity, relieved only by a few sparse gas-lamps. This state of things, apart from the inconvenience, as well as danger to the traffic, was utterly unworthy of one of the superb examples of architecture decorating the Place, and it became intolerable when two important departments became installed there; these were the Ministry of Municipal Government, and the temporary Post Office.

Fortunately, since the month of November last, the unsatisfactory condition of the Place was brought to an end by the inauguration of a system of lighting somewhat analogous, by the arrangement of the lamps, and the method of suspending them, to a part of the electrical lighting system in the city of London. This installation, the result of a contract to extend over one year, was made with the Administration of the city of Paris, by the work of the Compagnie Lyonnaise de Constructions et d'Eclairage Electrique, founded about a year ago, under the auspices of the Credit Lyonnais Bank, to work the Lontin, Berlin, and De Mersanne patents, and which has lately acquired the various Brush patents for France.

The lighting of the Place du Carrousel is effected by twelve standards of cast iron bronzed, about 20 ft. high, terminated at their upper part by a curved arm or bracket. This bracket, formed of two flat pieces connected by cross-bars, carries a globe containing two 8-millimetre carbons (or lamps, 8 millimetres in diameter, and about 40 centimetres long; they are covered with a copper coating, and the light is produced in the centre of a bead of ground glass, and placed in the centre with a small hole, that allows a passage for the dust resulting from the consumption of the carbons, and also for any condensed moisture or dampness. In this manner the light is diffused over the ground, without throwing any marked shadows. The length of the carbons is not narrowly limited, and the period of lighting may thus be very considerable, without the lamps requiring to be touched. The lamp is surrounded by a conical reflector, decorated by a mural crown, and by a series of the burners like those of gas-lamps, which form a special characteristic of this lamp, and which are fully illustrated and explained in our recent notice.

Fig. 1 is a sketch showing the design of the twelve standards, which are placed at the points marked *a a* on Fig. 3 around one part of the Place. It will be seen that this part of the installation does not light the whole of the main area, but only the portion between the entrance from the Rue de Rivoli and the gates leading to the quay; that is to say, the portion used principally by the public. This passage widens out into the wide area to the quay. It was therefore necessary to complete the lighting on this side in such a way as to make it uniform. This has been effected by placing at the refuge *o* opposite the principal entrance a post about 65 ft. high (see Fig. 2) formed of four standards, framed with angle-iron and lattice bars, at the top of which is fixed a double T-shaped bracket, carrying two regulators of the same type as the others, the luminous points of which are about 29 ft. from the ground. These lamps have an intensity almost double that of the others already described (nearly 2). The whole installation of fourteen lamps diffuses over the Place a pure white light of a highly satisfactory quality, and very uniformly distributed over the area, the light being sufficiently good to enable a woman's paper to be read with ease at any point. Compared to the prior condition of things the improvement is immense, and is fully appreciated by the mass of people constantly circulating there, who are now able to avoid the passing vehicles which were previously a source of continual danger. As far as the decorative effect is concerned, it is to be regretted that the very natural desire to deflect as much light as possible upon the ground should have led to the adoption of the De Mersanne louvre reflectors, which have the effect of masking out the lower parts of the façades of the pavilions on the Carrousel in such a way as to destroy the proper portions in complete darkness.

The electric current is generated in a large pavilion built in the vicinity of the temporary bureau of the Postal Administration behind the Tuileries gate. This building contains an installation of considerable importance, which is of sufficient capacity not only to illuminate the Place, but also the Pont Olfon, and the Prefecture buildings. It consists of two portable engines of from 35 to 40 horse power each, made by MM. Weyher and Richemond, of Pantin. They both of them drive one transmission shaft situated on the ground, and on the same level are the dynamo-electric generators which include two Lontin oscillating and two oscillating machines. One of these, which is nominally for 25 ampères, feeds 12 regulators on the Place; the other, for six regulators, supplies the two high lamps. Under the present conditions the generators absorb from 25 to 30 horse power. The other electric generators are four Brush machines, intended to feed each 16 lights, or 64 in all, of which 54 will be distributed in the different offices of the Postal Bureau; five will light the building containing the machines, and five others will be placed within the Prefecture. This part of the installation is not yet complete. As regards the lamps for the Prefecture and the Postal Bureau, the Brush lamps will form a part of the general scheme for lighting that building by different systems, which is now being worked out. According to the photometric experiments carried out by the engineers of the city of Paris, the twelve lamps have each an intensity of about 75 Carcels, and the two high ones in the middle of the Place, 125 Carcels each. The former are paid for by the Municipality, at the rate of 6 francs per hour per lamp, all charges being borne by the Compagnie Lyonnaise; the two others are paid for at an increased rate in proportion to their higher illuminating power.

tobacco-tax, the amount of which has not been as yet officially given. It is, however, known to be improved very materially by the treaty of commerce with Egypt. We may, therefore, rest assured that the revenues thus assigned are amply sufficient for the 1881 and previous loans, though certainly not sufficient to bear the strain of any large addition to the National Debt. Nevertheless, a large addition there must be when the whole of the "New" Loan is absorbed, and the annual charge is augmented by some millions of drachmas. For in the above tabular statement we have only 1,650,000 drachmas given as interest due for the half-year on the 170,000,000 drachmas loan; whereas, if the whole loan had been placed, it would have required 4,250,000 drachmas for interest alone. The total Debt charge would, therefore, be about 26,000,000 drachmas a year. It is true that the revenue assigned to the service of these loans collectively are estimated to yield upwards of 30,000,000 annually; but before any dependence can be placed on these figures, we must have more detailed returns, together with particulars as to further hypothecations, if any, and their probable yield.

While thus scrutinising the finances of Greece, it is but fair to take note of the manner in which the national resources are being applied. One of the first objects which the Government has in view is the abolition of the forced currency. This can only be done with advantage when a State has balanced its Budget, and restored income and expenditure to an equilibrium, a result which Greece considers it has now achieved. Next to that is the improvement in the means of internal communication,—a thing much needed, for of Greece it has often been summarily stated that it is a country without roads. Avoiding all rhetorical exaggerations, it may be said that when the Tricoupis Cabinet came into power there were in the country only about 1,200 kilometres of ordinary roadways, and one short railway of about eight kilometres, from Athens to the Piræus. Since then a line of railway of 12 kilometres, between Pyrgos and Catacolon, and another, the Volo-Larissa line, of 60 kilometres have been laid. Besides these, several important lines are in course of construction or under survey, and a special loan of 20,000,000 drachmas has been voted for the construction of carriage roads of the ordinary type. There can be no question that these measures will have considerable influence in the development of the resources of the country, and are much more commendable than the insane fit which seized it a few years ago, and which expressed itself in a mad effort to become a great military and naval Power.

ELECTRIC LIGHTING IN AMERICA.

No part of the expert evidence submitted to the Parliamentary Committee impressed the members of the Committee more strongly than that elicited from American witnesses. The lucid and confident manner in which the cost of lighting a square mile of London at a little under £100,000 was set forth, gave a high idea of the extent and success of Transatlantic achievements in electric illumination. Not for the first time, John Bull was deceived, not only as to the actual facts relating to the condition of things electrical in English cities, but also as to the state of affairs across the Atlantic. Facts were either misrepresented or withheld.

We have lately had the opportunity of examining, from unimpeachable sources, the cost and revenue of the only electric light station in the world which has seriously undertaken the task of competition with gas. We propose, therefore, to give our readers a brief history of this station from its foundation two years ago, with the financial results at the present time. Financially supported by the firm of Drexel, Morgan, and Co., and many of their clients and supporters—to the exclusion, however, of Messrs. J. S. Morgan and Co., who from the first declined any financial connection with the concern—Mr. Edison opened in New York, in September, 1882, the First District Illuminating Station. This portion of the empire city is the most densely populated part of the business or "down town" quarter. The area lighted is contained in a square of 2,400 feet, and last, therefore, an area of something less than a quarter of a square mile. The district contains about fifty blocks of buildings, and is intersected by some fifteen streets or passages. The necessary permission to open the streets to lay the electric mains was obtained, not by Act of Congress or by other legislative or official means, but by the simpler and perhaps less costly method of a payment to Tammany. The sum which passed amounted to about £10,000, and in exchange for this payment the Edison Company is free to tear about the streets whenever it pleases it so to do for electric lighting purposes. On September 4th, 1882, the station was started with 2,223 lamps, contained in about eighty-five houses. These lamps have increased in number until last month 12,540 lamps had been installed, the present capacity of the station being now attained. The largest number of lamps ever burning at one time was 5,530 in January of this year, and their average life, based on about 12,000 renewals, is a little more than 400 hours. Shortly after the installation of the station, it was found that some customers did not require the light in the summer, and that consequently their custom involved loss. It became necessary, therefore, to call from among the customers those whose demand was less than an average of 2½ hours per day for every lamp connected on their premises. If their consumption fell short of this standard, they were quietly cut off, so that the actual average consumption of light per lamp was artificially raised above the normal gas average of the district. This process of natural selection in New York is important, because, under the English Act, a customer using but half an hour's light in a month can not only claim to be supplied, but must, under grave penalties, be supplied by the unhappy Company. During the first year little money was received from customers, partly owing to the novelty of the enterprise, and partly owing to a natural desire on the part of the management that criticism should be disarmed before claims were lodged for the amount of the lighting bills. The cost of gas in the First District of New York is about 9s. 2d. per 1,000 cubic feet. Competition, therefore, with the other illuminant, having regard to the power of picking the good customers, and of unmeasured access to the streets, was rendered distinctly favourable. Added to this was the fact of Mr. Edison's presence, and the supply of ample funds for the purposes of the momentous experiment. These favourable elements notwithstanding, the financial result, when viewed from an impartial standpoint, is not only disappointing, but absolutely and finally disposes of any idea that electric lighting in England contains the germs of remunerative investment. Before giving the figures of the capital investment, running expenses, and revenue, it must be premised that the management of the station has been—at any rate during the period over which the returns in our possession extend—able, economical, and efficient. Not only is American genius more suited to the *exploitation* of new industrial developments than that of older countries, but there is a general disposition to help along a new scientific undertaking, which is signally wanting in England. The cost of the station is somewhat in excess of £200,000, and the annual expenditure is at the rate of nearly £16,000 a year, without allowing for depreciation, sinking fund, or interest on capital. The excess of receipts over actual cash outlay amount to about £6,000 a year, or 3 per cent. on the capital invested. When, however, a due allowance is made for unforeseen contingencies, such as the bursting of a boiler or other heavy casualties, it will be seen that the alleged profit is illusory, and if, at most, expenditure is equal to revenue, it is certainly not less. In order to appreciate the precise nature of the result of this experiment, it is necessary to suppose that each glow lamp is replaced by a five-foot gas-burner, and that the amount of gas consumed by customers be an equivalent of that consumed. The result of this calculation gives 6s. 11d. as the cost per 1,000 feet of the gas thus consumed. If, however, a sixteen-candle lamp be held to compete with a seven-foot gas jet, then the equivalent is as nearly as may be 5s. per 1,000 cubic feet. To compete with gas at 5s., the cost of maintenance—*i.e.* of production—must be reduced by two-thirds. On examining the means of reducing the cost of establishment, there is no reason to believe that any really efficient economy could be laid down in England for half the sum expended in New York; but it is improbable that the cost of maintenance can be materially diminished. From the foregoing, it is clear that such stations as the Victoria and Holborn installations, established by the Swan and Edison Companies respectively, or the Colchester experiment of the South-Eastern (Brush) Company, must inevitably lead to a permanent consumption of the available resources of the Companies in question. Finally, we are driven to the conclusion that, so far as central station lighting is concerned, the prospects in England are hopeless until a radical improvement in principle has been effected; and Boards of Directors maintaining the contrary, in the face of the evidence adduced on both sides of the Atlantic, incur a responsibility which, for our part, we are disinclined to share.

THE ELECTRIC LIGHTHOUSES OF FRANCE.

An admirable and very detailed account of the electrically illuminated lighthouses to be placed around the French coast has lately appeared in the columns of *La Lumière Electrique*. This account was written by M. A. Guérout, and is now substantially reproduced, together with the illustrations, from the pages of that valuable journal. The numerous lighthouses erected around the French coast are required to fulfil different services to navigation, and their importance varies, in consequence, according to the role they are called upon to play. They have in the first place to indicate to the navigator the proximity of the coast, and the lighthouses erected with this object are placed in preference on the more advanced capes and promontories which form, as M. Guérout puts it, the points of the polygon enclosing the coast. These are the most important and prominent, and are called lighthouses of the first order. Between these main signals which indicate the contours of the shores, there are many more accentuated points, but not so prominent, which serve as the locations of lights of less importance, and guide the navigator to the entrance of the port he is making. These are the lighthouses of the second order, called as not only on account of their position, but because of the smaller intensity of the light that they project. Between these points again are others, the position of which is of importance to show; these may be sandbanks, reefs, sunken rocks, islets, &c. According to circumstances, such points are signalled by lights of various powers, classified into the third, fourth, and fifth orders. Finally there are the lamps which mark the positions of jetties and the more insignificant ports. Passing to another classification based on both sides of the Atlantic, incur a responsibility which, for our part, we are disinclined to share.

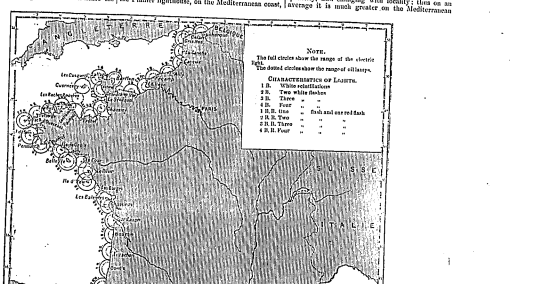
THE ELECTRIC LIGHTHOUSES OF FRANCE.

As admirable and very detailed account of the electrically illuminated lighthouses to be placed around the French coast has lately appeared in the columns of *La Lumière Electrique*. This account was written by M. A. Guérout, and is now substantially reproduced, together with the illustrations, from the pages of that valuable journal. The numerous lighthouses erected around the French coast are required to fulfil different services to navigation, and their importance varies, in consequence, according to the role they are called upon to play. They have in the first place to indicate to the navigator the proximity of the coast, and the lighthouses erected with this object are placed in preference on the more advanced capes and promontories which form, as M. Guérout puts it, the points of the polygon enclosing the coast. These are the most important and prominent, and are called lighthouses of the first order. Between these main signals which indicate the contours of the shores, there are many more accentuated points, but not so prominent, which serve as the locations of lights of less importance, and guide the navigator to the entrance of the port he is making. These are the lighthouses of the second order, called as not only on account of their position, but because of the smaller intensity of the light that they project. Between these points again are others, the position of which is of importance to show; these may be sandbanks, reefs, sunken rocks, islets, &c. According to circumstances, such points are signalled by lights of various powers, classified into the third, fourth, and fifth orders. Finally there are the lamps which mark the positions of jetties and the more insignificant ports. Passing to another classification based on both sides of the Atlantic, incur a responsibility which, for our part, we are disinclined to share.

with varying conditions; thus some signals placed in the sea project their light in all directions; others standing on a point of land, concentrate their rays within a certain angle; others again illuminate only a given point; hence the definition of lighthouses for the full horizon, for three-fourths, two-thirds the horizon, and so on.

Until 1863, all the lighthouses on the French coast lighted with oil, and it was only during the year just named that one of the two signals at La Hève was lighted by electricity. After an experience of some year and a half, an experience which was in all respects satisfactory, it was decided to extend the same system to the second of the La Hève lighthouses. This also worked excellently, but nothing more was done in this direction until 1874, when the electric light was installed at Cape Grisnez. Again a long delay took place, and no further progress was made, although in this country six lighthouses were electrically illuminated. Quite recently, however, it having been found necessary to reconstruct the Planier lighthouse, on the Mediterranean coast, not far from Marseilles, it was decided to adopt the electric light in the new structure, and to take the same course with the Palmyra signal, the power of all on the Channel. which was quite insufficient. Both these important installations may now be regarded as complete.

The satisfactory results obtained with the electric light at La Hève and Cape Grisnez, called attention to the more general services the system could offer, and on the 27th January, 1880, after a long study of the question, M. Allard, director of the French Lighthouse Department, presented to the Minister of Public Works a report recommending the general adoption, on all the French coasts, of the electric arc for lighthouses. This report was approved on December 8, 1880, by the Lighthouse Board, and on March 3, 1881, by the Council General des Ponts et Chaussées, and the principle of electric lighting has become universal for grand-



NOTE.

JAN. 26, 1883.] ENGINEERING. 91

ELECTRIC LIGHTING IN SHEFFIELD.*

Preliminary Report of COLONEL W. COOKE, *Member of the Institution of Engineers and Architects of Electricians.*

The Corporation of the borough of Sheffield having received a reply to the effect that they could not obtain a provisional order under the Electric Lighting Act of 1882 for a provisional district to supply electricity for public and private purposes within the said borough, and having been requested by the Council to report to them as to the best means of establishing a system of electric lighting, I have the honour to submit the following preliminary report.

The application of the science of electricity to industrial purposes, especially to the production of artificial light, is a question, the importance of which is daily increasing, and the skilled industries of electro-plating and electrotyping, which have been in use for years, stands out in prominent proof that it may fairly be said to have passed from the experimental stage. Many of the most eminent physicists to take the lead among the scientific industries of the world; and the International Exhibitions held at Paris in 1878, and still more emphatically the Exposition of Nuremberg, which was held in the same city last year, have demonstrated beyond the possibility of question the value of the application of electricity to illumination as well as to other handicraft requirements, and the practical success of these practical demonstrations has been such that a strong and insatiable public demand for electric light has arisen, and a large and rapidly increasing number of electrical installations have sprung up in every civilised portion of the globe, not only in but for years, such as in France, Belgium, and Germany, and in the United States of America.

The lighting of a considerable number of the streets of Paris and London was quickly followed by that of the public and a new branch of industry was created, which, by its wide and vast sunplicable fast electric lighting companies, which sprung up in the opposite countries of the world, and enormous fortunes have been formed in benefitting by the new discovery. The success of so many public undertakings is a sufficient antidote to brain pressure, and the effect which was sought in a reduction in the number of the Board of Trade will be entirely defeated by the proposed provisional orders.

Since the commencement of the issuing of this Act it has been the endeavour of nearly all the important towns in the United Kingdom to be supplied by and secured with notices from some firm or electric lighting company, or other proprietors of systems of electric lighting, with the object in view to apply for licenses or provisional orders for the establishing, in each of the towns applied for, of a more or less gigantic system of electric lighting machinery, with powers for the breaking up the public streets and highways, and for placing and fixing the conductors or electric mains, and for the doing of all such things as are necessary to the efficient working of such installations upon a large scale.

The giving consent to the obtaining of provisional orders for such purposes to private companies or bodies, would virtually amount to the abandonment of the rights of the local authorities and other local authorities in the control of the streets and highways, within their own boroughs or districts, over which they have hitherto exercised, and would have otherwise, if they had been left to a very general and very decided feeling on the part of the provisions and other local authorities, to resist or exercise an interference with their rights within their respective districts.

To prevent this interference, there appears to be but one course open to the local authorities, and that is for each district, and that is the course which Sheffield, with the Board of Trade Rules), themselves to apply for a provisional order for electricity supply in their own districts, and then maintain in their own hands the control of the streets and highways, and at the same time to put their local authorities in a position to exercise the same powers throughout the train being equal to 512 standard candles. The lamps are of 42 volts E.M.F., and the motion of the train appears not to have affected their durability. It was almost expected that the jolting of the train would have proved injurious to the accumulators, but experience has shown that they have worked more continuously satisfactory in the train than in installations where they remain unmoved. The connections between the carriages are so made as to be easily joined together, and to sever by the mere slip of the carriages. The system is entirely automatic, and practice has shown that the apparatus requires no attention whatever beyond occasional lubrication. Another important feature in the arrangement is that the apparatus is autonomously reversible. Consequently it works equally well, no matter in which direction the train is running. The electric light was installed in this train by the Railway Electrical Contractors, Limited, of 4, Great Winchester Street, London. The train commenced running on December 10, 1883, and has been in work

OTHER ITEMS IN SCIENCE.

Arrangements of the controversy now raging, and as from being ended, with regard to over-pressure in s it is a noteworthy fact that the question of how pretty constant the generally depressing effects of ster-strikes and lock-outs is now being seriously con sidered, and the measures there taken, if acted should be remunerative here. Official action reference to over-pressure has been taken in B Wurtemberg, Baden, and Alsace Lo Experience in German schools—and the same has doubtedly been found in those of other countries —has shown that physical exercise alone is

The Corporation of the borough of Sheffield having received a reply to the effect that they could not obtain a provisional order under the Electric Lighting Act of 1882 for a provisional district to supply electricity for public and private purposes within the said borough, and having been requested by the Council to report to them as to the best means of establishing a system of electric lighting, I have the honour to submit the following preliminary report.

The application of the science of electricity to industrial purposes, especially to the production of artificial light, is a question, the importance of which is daily increasing, and the skilled industries of electro-plating and electrotyping, which have been in use for years, stands out in prominent proof that it may fairly be said to have passed from the experimental stage. Many of the most eminent physicists to take the lead among the scientific industries of the world; and the International Exhibitions held at Paris in 1878, and still more emphatically the Exposition of Nuremberg, which was held in the same city last year, have demonstrated beyond the possibility of question the value of the application of electricity to illumination as well as to other handicraft requirements, and the practical success of these practical demonstrations has been such that a strong and insatiable public demand for electric light has arisen, and a large and rapidly increasing number of electrical installations have sprung up in every civilised portion of the globe, not only in but for years, such as in France, Belgium, and Germany, and in the United States of America.

The lighting of a considerable number of the streets of Paris and London was quickly followed by that of the public and a new branch of industry was created, which, by its wide and vast sunplicable fast electric lighting companies, which sprung up in the opposite countries of the world, and enormous fortunes have been formed in benefitting by the new discovery. The success of so many public undertakings is a sufficient antidote to brain pressure, and the effect which was sought in a reduction in the number of the Board of Trade will be entirely defeated by the proposed provisional orders.

Since the commencement of the issuing of this Act it has been the endeavour of nearly all the important towns in the United Kingdom to be supplied by and secured with notices from some firm or electric lighting company, or other proprietors of systems of electric lighting, with the object in view to apply for licenses or provisional orders for the establishing, in each of the towns applied for, of a more or less gigantic system of electric lighting machinery, with powers for the breaking up the public streets and highways, and for placing and fixing the conductors or electric mains, and for the doing of all such things as are necessary to the efficient working of such installations upon a large scale.

The giving consent to the obtaining of provisional orders for such purposes to private companies or bodies, would virtually amount to the abandonment of the rights of the local authorities and other local authorities in the control of the streets and highways, within their own boroughs or districts, over which they have hitherto exercised, and would have otherwise, if they had been left to a very general and very decided feeling on the part of the provisions and other local authorities, to resist or exercise an interference with their rights within their respective districts.

To prevent this interference, there appears to be but one course open to the local authorities, and that is for each district, and that is the course which Sheffield, with the Board of Trade Rules), themselves to apply for a provisional order for electricity supply in their own districts, and then maintain in their own hands the control of the streets and highways, and at the same time to put their local authorities in a position to exercise the same powers throughout the train being equal to 512 standard candles. The lamps are of 42 volts E.M.F., and the motion of the train appears not to have affected their durability. It was almost expected that the jolting of the train would have proved injurious to the accumulators, but experience has shown that they have worked more continuously satisfactory in the train than in installations where they remain unmoved. The connections between the carriages are so made as to be easily joined together, and to sever by the mere slip of the carriages. The system is entirely automatic, and practice has shown that the apparatus requires no attention whatever beyond occasional lubrication. Another important feature in the arrangement is that the apparatus is autonomously reversible. Consequently it works equally well, no matter in which direction the train is running. The electric light was installed in this train by the Railway Electrical Contractors, Limited, of 4, Great Winchester Street, London. The train commenced running on December 10, 1883, and has been in work

It is necessary that the Corporation, in applying for a provisional order, shall undertake, within a specified time, to give a supply of electricity for private purposes within the district to which the area, with which the order may apply, if required to be compared with the area of the whole borough; but the Corporation may limit the area to be supplied, and thoroughout to supply at a uniform rate of remuneration any intending consumer within such area.

I would therefore propose that the Corporation should, in the first instance, limit the provisional order, required to make an immediate lighting of a certain limited area of the town, and that the area to be so chosen should be the Corporation, or portions from such stations situated respectively at or near the opposite corners of the area to be lighted. The district I would recommend should be limited in its boundaries to a preliminary area, and in order to meet the object of the Board of Trade, that the streets of Sheffield extending, generally speaking, from north-east to south-west, and from south-east to north-west of Worksop, were to be lighted, from the river end, and of Pinstone-street, near to Moorhead, to the suburbs of Broomhall-street, near to Moorhead, to the suburbs streets and thoroughfares, the houses and other buildings in which the electric light should be included in the area of electricity supply :—(1) Wainsgate; (2) Castle Folds; (3) Haymarket; (4) Waingate; (5) Castle Green; (6) Hartshead; (7) Market-place; (8) Market-street; (9) High-street; (10) Churchyard; (11) Fargate; (12) Church-street; (13) Angel-street; (14) Tudor-square.

The above series of streets measures in the aggregate about 2 miles of house frontage, 75 per cent. of which is occupied by shops.

Leaving for the present consideration the public lighting of the above district, I will now proceed to the question of the domestic and general lighting of the houses and other buildings in the streets of which it is composed, and the houses and premises which present the best field for consideration is whether the illumination shall be effected by are lights or by incandescent lamps, or by a judicious combination of the two. There cannot be a doubt that, for large open spaces, for large halls, and for other buildings of similar class, the electric arc light is the most economical, and, on the other hand, that for small rooms, as in private houses, the incandescent lamp is the most convenient; but, on the other hand, there is a class of buildings which occupy a position of middle importance, and the lamps employed require to be fitted with new carbon points every 8 hours, and not only have the carbons to be supplied, but also such adjustments have occasionally to be made to the lamps as can only be effected by a skilled workman. I would not recommend to them, are such as would prevent my recommending any system of lighting for private purposes lighting, for which my reason it is impossible for the apparatus within a private house to be placed in safety, being as it is more or less in the hands of domestic servants and other unskilled people.

For the purposes of public lighting I recommend for the general lighting of the district the employment of lights for by incandescence, of which, as the Corporation will have seen several systems, except by many objections, which I would therefore recommend the laying out of the illuminating as if nothing but incandescent lights were to be employed; but I would, at the same time, point out that, in the event of the Corporation determining to make the employment of arc lights in certain streets where they might be more suitable; for it is quite possible that the Board of Trade may consent to a substitution or are lamp for a corresponding number of incandescence lamps, and thus have both are lights and incandescent lamps, and thus have some circuit. I should prefer (if there were a demand for it) that the supply should be given by a battery, the laying of a separate circuit for them, and, instead of employing a dynamo machine or series of machines, I would recommend that there would be specially constructed a machine whether this should be done or not can only be determined by the local authorities and other local circumstances.

The standards required with incandescence lights is similar to that of gas, there, on or off, as required, and the lights will be entirely free from destroyed; and as the average life of an incandescence lamp is stated to be practically at 1000 hours, and as renewal is so simple as practically to convert gas-fittings into a confidential, the attention required to be given to altogether inconsiderable, and the cost even trifling incidents any lighting operation except the turning on of a switch or the lighting of a gas.

The efficient and steady illumination there is nothing to be desired in incandescence lighting when perfectly steady, being subject to no fluctuation—as cannot be said of the very best are lamp at present in existence—although all the are lamps employed to any considerable extent at the present time are great improvements on those of a few years ago; and I have no doubt are lighting will be still further improved by the introduction of regulating lamps will no doubt be introduced, and also by side with those improvements, the system of the self-adjustment of dynamo machines to the work put upon them, from time to time, will become more and more developed.

To arrive at any thing like an accurate estimate of the amount of illumination required—that is to say, of the number of lights of a given intensity—also of the number required to be supplied with electricity—I would suggest that the following be adopted:—Assuming that the streets to be lighted in the manner of lights they would require (estimating at one-candle power for each compound) or, if that be considered inadvisable, a different number of lights, according as nearly as possible, the number of gas-lights at present existing in the above and other buildings attached to the streets mentioned in the schedule, and from an estimate as to the number of lights which the houses in the above streets might be expected to be in the case of each information, and for the purpose of the requirements of the installation, I have taken an average number of 5 lights to each house in the district by one-candle power lamps; and upon this assumption, during 1 light is that there are 500 average houses, or, say, 2500 lights in a district consisting of private dwelling-houses and 5 or more stories, it is fair to estimate that the average number of 16-candle lamps may be effected by allowing an average of one lamp to every house of an average frontage of 25 feet, on which calculation there would be required 5000 lamps. I assume, however, that the principal thoroughfares of the streets set forth in the schedule on page 2 of this report is crossed, in as large a proportion as 1 in 10, there would be a large number of lights, I think it would be hardly safe to estimate a smaller number of lights per house than 5, and I therefore adopt that number as the basis of my calculations, or 10,000. It is not in the least degree probable that the streets mentioned in the schedule would be lighted at the same time, but I assume that there will be a considerable number who will desire to have lights after midnight. On the other hand, there will be others who will expect many among the proprietors of important shops will require a considerably larger number of lamps than the ordinary dwelling-houses, say eight lamps for every 25 ft. of frontage, and so the additional lights will make up for the deficiency mentioned in the last paragraph, or about 10,000 lamps.

To drive these 10,000 lamps, I estimate, would require about 1000 horse power, and these would be worked together. The dynamos selected at about an eighth of a horse-power per lamp, but I am inclined to think that this would generally be proportion of a horse-power of incandescence system, when, as a rule, state that an average of 10 lamps per horse-power is the most that can be relied on. I do not feel justified in recommending the adoption of a less number than 10 lamps per horse-power for every light in the district, as in outside cases, and should allow a margin for inefficient lamps.

I would here point out that, in most of the recognised incandescence systems, the carbon filament is terminated by a corresponding variety of carbon, and therefore of fuel consumed; so that, if at any time 100 lamps are in operation, or 1000, or 10,000, the power absorbed will bear a proportionate relation to the number of lights in action.

(To be continued).

THE PHOSPHOR-BRONZE COMPANY, LIMITED.—We understand that Mr. James Wallace, C.E., of Augustine, the consulting electrical engineer and inventor of silicium bronze, has joined the board of directors of the Phosphor-Bronze Company, Limited.

IRON MANUFACTURE OF FRANCE.—It appears that the imports of iron minerals into France in the first nine months of this year amounted to 1,062,440 tons, while the total Belgium contributed 65,728 tons; Germany, 265,000 tons; Algeria, 377,360 tons; Italy, 91,000 tons; Spain, 217,520 tons; and other countries, 891 tons.

IRON AND STEEL SECTIONS.—Messrs. Bailey Yeas and Co., of Sheffield, Northern Foundry, 171, Corporation-street, have issued a pocket edition of their list of angle, bulb, tee iron and steel, English and foreign sections, and round channel and deck beam. It contains particulars of nearly 1000 sections that can be rolled in iron, many of which are also marked as being procurable in steel, and is published in a form adapted to be hung upon the wall. To those using rolled iron it will be of considerable value, as it will show at a glance what sections can be obtained. The information concerning steel sections is particularly useful at the present time.

PUBLIC WORKS.—At a meeting of the Civil and Mechanical Engineers' Society, held on the 16th inst., the president, Mr. Herbert Wright, M.I.C.E., in the chair, a paper was read by Mr. H. Mitchell Whitley, C.E., "On the Best Method of Conducting Public Works in the Great Britain." The author directed his chief attention to the terms by which landed property is acquired for the purposes of public works by compulsory power, to one of the main objects of an Act to construct public works, after discussing which, the procedure before Parliament was described, especially the preparation of the Parliamentary plans, and the deposit of the Bill. The author then went into detail if possible to allotted to the subject, especially especially insisted on the need of accuracy in all portions of the work, considering the rigorous examination to which plans are subjected before the sanctions of Parliament is given. The paper dealt with the subject of the estimate, and the method of receiving the tenders, and concluded with an Act of Parliament. A discussion ensued, in which the President and Messrs Bird, Mumday, Walton, Whittaker, Brewster, Burbridge, and Child took part.

THE ELECTRIC LIGHTHOUSES IN FRANCE.

(Continued from page 398).

The Planier lighthouse; see Fig. 1 (page 626), has just been completed, and is situated eight nautic miles from Marseilles, on a rock, the plan of which is shown in Fig. 2. It consists of a tower 19·6 ft. high, and 23 ft. 6 in. in diameter at the base, and springs from the rock at a level of about 16 ft. above the sea. As will be seen from the plan the tower and adjacent buildings are protected by a surrounding wall from the action of the waves; from this exercise an open gallery, protected by sea walls, leads down to the little harbour shown on the plan, on which the following reference figures will be noted: 1 is the new tower now being

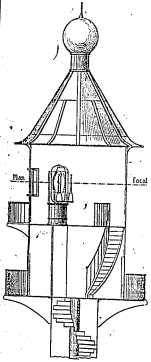

FIG. 14.

described; 2, the engine and generator house; 3, the old lighthouse; 4, an old tower; 5, the 6, is an inclined plane; 7, the tarbinet; 8, a tank-water; and 9, is the exercise above referred to. Fig. 3 is a section of the louvers at the top of the tower, and Fig. 4 is an enlarged view of the lamp; in the latter figure are shown, the fixed light apparatus, and a mechanism for driving this latter is also shown in some detail. In this installation the changing of a regulator is also effected by means of two pairs of rails, but they are not placed at an acute angle like those in Le Hâvre. One of them enters direct into the optical apparatus; the other is placed outside and

As light angles to the first; at this point or junction is a turntable, and with this arrangement the time required for shifting is not longer than with the method as La Hâvre. The De Meritens machines which feed the regulator are fixed in the room marked 2 on the plan; and enlarged views of the installation is given in Figs. 5 and 6, page 634, which are respectively a plan and longitudinal section. These views will explain themselves, with the help of the following reference: *a* is the engine and boiler house, the two boilers being of a vertical type; *b* is the electric generator room, which contains also the transmission shaft, from which motion is taken off the engine and transmitted to the generators; *F* is a forge and heavy repair shop, there being a second adjoining the generator room for the more delicate work connected with the electric machines; *c* is a water tank, and *d* a coal depôt, with a second water tank beneath.

The Planier is a full lantern lighthouse, throwing its rays in all directions. Its distinctive character is that of three white flashes, separated by one red flash, and its range, like that of all the new Mediterranean signal towers, is 27 nautic miles for fourteen-fifteenths of the year.

As the electrical installation at this lighthouse is the newest and most complete in France, some details of the arrangement will be found of interest. The plan, Fig. 8, shows clearly the position of engines, transmission shafting, and generators. The latter are both placed on the same masonry foundation, and the axes of the two machines are in the same line. These generators are not intended to be both worked at the same time; however, that one may be always ready to replace the other in case of accident, both shafts are keyed together, and both machines are driven, the one idle, the other with a closed circuit. Each generator is divided into two circuits, represented by four terminals placed as the upper part of the frame, two at each end. The terminals placed one beside the other at each end of the machine are those which at a given instant form the poles of the same name. From each of them is led a copper conductor taken down along the masonry foundation, and following the ground as shown in Figs. 7, 8, and 9, till it arrives at a commutator placed on the column that carries the transmission shafting. One object of the commutator is to take the current either from generator No. 1 or No. 2; another is to couple either in tension of quantity the two circuits of each machine. The four possible combinations of this commutator are shown in Fig. 10, from which it will be seen that the opposite couples of fixed and movable contacts arranged in a circle. The fixed contacts are fourteen in number, four of them on the left are in relation with the terminals 1, 2, 3, 4, from which are led the conductors of the generator on the left, or machine No. 1. The four corresponding contacts on the right hand are connected with the terminals corresponding to the conductors from machine No. 2. The three upper contact pieces belong to the terminals communicating with the conductors leading to the lamp. It should be mentioned that the return current is led off from the lamp by a large cable after traversing the sea, which it has reached by two smaller cables, in one of which is placed the electro-magnet of the lamp. Of these three upper contacts, the one on the left communicates with the terminal 3, to the next is connected the conductor of the electro-magnet just referred to, the next belongs to the terminal F G of the second small conductor; lastly, the piece on the right, half as large as the others, is in communication with the terminal G C of the large cable. The system of fixed contacts is completed as the bottom of the circle by three pieces, the centre one of which is twice as long as the others; the two side ones communicate by auxiliary conductors, that on the left with the contact piece of the terminal 2, that on the right with the contact piece of the terminal G C.

The movable contacts to the number of eight are also shown in Fig. 10; they are all carried on one plate, free to move around the centre of the apparatus. The innermost pair of contacts are connected together in such a way as to form the letter C; the next outer pair is similar, and the four letters are connected two and two by the metallic strips, concentric with the centre of the commutator. A handle in the middle of the movable plate serves to place it in different positions. Supposing that the movable contacts 1 and 2 are as shown in the diagram in the first position for quantity. The terminals 1 and 2 being at the same instant poles of the same name, the current enters simultaneously by these two movable contacts corresponding to them terminals, and passes thence into the small cable and the cable in which is the electro-magnet. After passing the carbons it is collected into one conductor and returns by the large cable to the terminal G C. On the first contact of double the size, in connexion with this terminal, the two movable contacts rest, by which the current returns to the terminals 3 and 4. In coupling for tension in the same machine the current, leaving the first circuit of the generator by the terminal 1, traverses the most extended pair of movable contacts, and arrives at one of the inner fixed pieces by means of a conductor auxiliary to the terminal G C. It then follows the large cable, passes through the carbons, and then traverses only the small conductor and electro-magnet to arrive at the terminal 3; thence by the second auxiliary conductor to the smallest movable pair of contacts and to the terminal 4. It flows then through the second circuit of the machine, returns to terminal 3; afterwards by the second pair of movable contacts it arrives at the large central bottom contact piece, whence it is conducted by the third movable contact to the terminal 2, and in this way to the first circuit of the generator. In following out the positions of the movable contact indicated in Fig. 10 for the second generator, the direction of the current will be seen to be similar. The contacts are covered by an ebonite disc through which passes the handle serving to manipulate the movable plate; this ebonite disc carries four inscriptions corresponding to the various combinations of the commutator, and a movable index on the handle indicates by its position against one or other of these inscriptions what the actual combination is.

This system of commutator has the advantage of permitting an instantaneous change in the grouping of the two dynamos of the same machine, and of exchanging instantly one generator for the other; the arrangement, however, presents the drawback common to all turning contacts of not being absolutely reliable.

Figs. 11 and 12 show a modified commutator also employed for the De Meritens machines, and which has been fitted to lighthouses in this country. In this arrangement the terminals to which the lamp conductors are connected and the cables from the machines are practically in the same relative positions as in the previous one. From these terminals pass strips of copper which can be locked in position by the handle shown, and these unite on the terminals. The locking pieces in connexion with the generator terminals can be connected with copper strips by the locking screws corresponding to the lamp cables, and by facilitating or impeding by the locking levers are more or less raised in order that the strips may come each either without touching. In the way absolutely perfect contacts can be obtained, but the idea presented is one to be noted as the system combined is longer than with the revolving contacts.

We have already described and illustrated (see Fig. 5, page 597 *ante*) the rails on which the regulators are placed by which they can be exchanged. Fig. 13 on page 634 is a further illustration of this arrangement. These rails are in direct communication with the large cable, and it is thus that the current arrives at the frame of the regulator, and thence to the carbons. The regulator itself is a combination of the Serrin and the Berjot lamps, the former of which is well known, and the latter we have recently described and illustrated. It comprises the two electro-magnets of the Berjot lamp, the armatures of which form an internal core, one magnet having coarse wire, and placed direct in the circuit, the other a fine wire magnet, mounted in a derived circuit. The former acts on the articulated frame carrying the lower carbon; the other influences the disc brake that controls the clock train.

As has been already mentioned that the transformation of the Palmyre lighthouse is complete, the Hâvre do is now in progress; this, unlike the Planier, will throw a beam only in one direction, and the arrangement of its lantern is therefore different, being as indicated in Fig. 14, the general disposition resembling that of La Hâvre. The optical apparatus for the new fixed lights will be 2·3 m. in diameter, instead of 1·91 that figure which was the old one. With the revolving cylinder of vertical lenses the diameter reaches 2·36 m.

Before concluding this article we will give the following data regarding electric illumination for lighthouses in France tabulated from the report of M. Allard, and which will be found of interest.

J. Illum. Engin. Nov. 27/84

Electric Lighting.

The rapid growth of the business of the companies engaged in electric lighting, and the general progress which has been made in the art as indicated by the patents which have been granted, and the improvements which have been made in the appliances for lighting, are subjects of general remark. The literature of electric lighting has developed, perhaps, with just as great rapidity as the art itself. The number of works that have been issued is phenomenal, while the catalogue put out by the different companies and which explain in detail the different systems evince an enterprise in this direction that is scarcely paralleled in any other line of business. An example in point is a small quarto pamphlet recently issued by the United States Electric Lighting Company, whose New York office is at 59 and 61 Liberty street. In paper and typography this book compares favorably with some of the finest publications to be found in the regular book trade, while the illustrations displayed have been done in the highest style of the engraver's art. Each page is embellished by a red-line border, and, altogether, the book is one of the most attractive trade publications which it has been our fortune to examine. It would be impossible in a notice of this kind to describe the contents of the work satisfactorily, for nothing short of a presentation of its entire subject matter would be adequate. The Weston incandescent system is the principal subject discussed, and the various appliances used in lighting it, with numerous pictorial illustrations of large full size, are described. Instructions as to the method of wiring buildings, switching brackets for use in office and factories are also carefully shown. The arc lighting produced by this company is also illustrated, although not so fully as the incandescent system.

Engineering, Nov. 28, 1884.

the phenomena in question resolve themselves into very simple elements when the facts of the case come to be carefully analyzed, and the recent boiler explosion at Hilston, to which we briefly referred in our issue of the 14th inst., and further particulars of which will be found in another column, offers no exception to the rule in this respect. In fact it may be taken as a very typical case of what usually occurs in such disasters. In this case three plain egg-ended boilers in a range of ten set side by side exploded in all appearances simultaneously and scattered their fragments all around.

It is easy to understand that to the untrained observer who judges only from general results, the fact that the boilers were almost new, that no wasting of the plates was visible, and that at the time of the explosion the boilers which burst were working in conjunction with five others alongside which remained uninjured, may present itself as a puzzle by no means easy to solve. To the trained expert, however, accustomed to investigate such phenomena, the disaster did not present much difficulty of explanation, and was comparatively easy to diagnose.

A careful examination of the fragments revealed the fact that in one boiler, and in one only, was there a longitudinal rent, which in the skilled eye had been very severely overheated, and on plotting the position of the rent it was found that it had occurred just at the part which would be overheated in the event of the level of the water in the boiler getting too low. Further consideration showed that it was not probable the shortness of water had been brought about by evaporation in the ordinary way in consequence of the steadiest neglecting his feed supply, but that the lead had been in all probability melted very rapidly from some cause or other, and the evidence of Mr. Morten and Mr. Ramsay at the inquest showed, we think, that the most probable explanation of the loss of water was that the leakage had occurred at a defective joint in the blow-out pipe.

We find that a portion of the blow-out pipe on the boiler was made of wrought iron, while those of the other two were of cast iron, enabled it to be identified as the middle boiler of the three which had burst. The evidence, therefore, showed clearly that in the case of No. 2 boiler at least, the explosion was due to the fact that the water had become exhausted, so that a shearing action is set up whereby a heavy strain is thrown upon the ring seams of rivets, and we have frequently known boilers of this class to explode in consequence of a sudden steam rip starting at the ring seams of rivets in this way.

Barring these facts in mind, therefore, all mystery in connection with the Hilston explosion vanishes, and it is easy to understand how the shock consequent on the bursting of No. 2 boiler from absence of water should have so severely strained the adjoining boilers on each side of it that they exploded in turn. A reference to the plan of the exploded boilers, which we give on page 591, will show that the circumferential rents in the two outside boilers occurred at the part which would be called upon to bear the greatest effect of the blow consequent on the bursting of the middle one. There would in reality be two, if not three, explosions, but the interval of time between each would be so short that they would appear to be simultaneous rather than successive.

The explosion at Hilston is not the first instance in which several boilers have burst together, though happily the occurrence of these disasters is somewhat rare. From the printed reports of the chief engineer of the Manchester Steam Users' Association, it appears that this is the tenth compound boiler explosion which has been recorded in the United Kingdom since the year 1862. The last occasion on which a disaster of this kind occurred was in March, 1879, when six boilers, all of the plain egg-ended externally fired class, went off together. In that case one of the boilers was ripped into a great number of pieces, which were scattered around in all directions, while each of the other five were only divided into two or three pieces at the ring seams of rivets, and the fragments were simply shot fore and aft. Investigation showed that in the case of the boiler which was torn into a great number of pieces the outlet for the steam had been plugged, in consequence of which the pressure had gone on accumulating until the shell gave way, the shock consequent on the explosion being so violent that the five other boilers set alongside also gave way. Another very similar explosion to this occurred at St. Helen's in 1872, when three boilers of the plain egg-ended type failed in consequence of the outlet of one of them being stopped with a wooden plug. On looking over the list of these compound explosions given in Mr. Fletcher's reports, it appears that in no less than six out of the ten cases recorded the boilers were of the plain cylindrical type fired externally, a fact which would seem to show that boilers of this class possess elements of danger that are hardly shared by those of the internally-fired description. That the boilers at Hilston, for instance, been of the Lancashire or Cornish type, the occurrence of shortness of water would in all probability not have involved anything more serious than a collapsed furnace crown. The boiler in question, and could certainly not have resulted in the bursting of two others alongside.

We may just add in conclusion that the Hilston explosion, enforces still more upon steam users the importance in dealing with steam boilers of carefully considering every detail in their design and equipment. The shortness of water was in all probability due to leakage at the joints of the blow-out pipe, which was concealed and heated for that, instead of being open, and free to move with the boiler, while the disastrous consequences would have been averted had the boiler been furnished with a reliable feeding for giving warning in the event of the water in vogue a steam boiler cannot be too well equipped to begin with, nor too vigilantly watched when set to work.

THE ELECTRIC LIGHTING COMPANIES.

Just two years ago the electric lighting companies were besieging the Board of Trade for provisional orders, and were dividing the country among themselves, much as the Israelites had done under Joshua, marked out the promised land before they set foot in it. Every town, which was awarded to one or other of the companies, while London, with its many centres, was more or less equitably divided among several of the principal. The process was not without its expenses, but at a time when investments at 4 per cent. were most difficult to find, it was considered worth while to risk a good deal to obtain possession of a monopoly.

Engineering, Nov. 28, 1884.

would not have a shadow of chance against two of them. In such a case our Mediterranean fleet would have to keep together for mutual protection, but they should fall in with these powerful vessels, when escape would be impossible, having neither speed to run away, nor being a match for fighting; the result would be that our boasted Mediterranean fleet would command a little piece of water extending no further than the range of its guns. On the other hand, the Italian ships might disperse without the least anxiety as to the result, for we have no vessel that could overtake them and then fight them when caught, yet they could catch any of our vessels with ease and destroy them in detail. As for the Indefatigable, she might well, in such a war, be classed with Malta and Gibraltar, and so far as destroying the enemy's ships is concerned, would be no nucleus, for they would keep out of her way, while a ten-knot ship, however handy, cannot overtake another that steams fourteen.

It is most important that something be done to remedy this glaring defect in our Navy; it is very easy to say that building an enormous ship is the cheapest way to carry a given number of men and carrying too many eggs in one basket, or some may say they cost too much money; but if, without considerable additions, our existing navy is useless, all the money hitherto spent is wasted to no purpose. As to expense, the Inflexible cost nearly a million and a half, with all her absurd complication of machinery, and for the same money two vessels like the Dublin, but with more speed, might have been built, if only the Admiralty could be taught to construct vessels in the only way that private enterprise can do business, well and at a reasonable cost.

When the Italian Government commenced the enormous coast. If the constructive department is unable to prepare suitable working drawings, the sooner it is abolished the better, and private firms or foreigners will readily supply all that is necessary.

These alterations to old ships refer not only to improvements, as they are called, respecting armour and guns; but of late torpedoes have made their appearance, and are destined to play a prominent part in the naval warfare of the future, and there is a tendency to adopt all kinds of inventions for the protection of our ships, little regard being paid to the serious consequences they will entail in other respects. In the contemporary before alluded to, a plan has been proposed for protecting our ships by means of steel rods screwed into their sides, sufficiently strong to support a network of smaller rods, which shall surround the vessel, and extend a few feet under water; this apparatus, it is computed, will not reduce the speed of our already too slow ships, more than two or three knots per hour; this sounds quite feasible, at the same time it is quite delightful to conceive the idea of our ironclad fleet, dressed up in petticoats, sitting in state in the middle of the Mediterranean, waiting patiently for the enemy to attack it, the admiral's lady wearing a plaid suite of corset as he watches a few of our vessels being burnt in the distance, and thinks what a thrashing he will give those wretched foreign cruisers—when he catches them. But this is too serious a subject to laugh at, something must be done, and that at once. Foreigners have fully appreciated the importance of these abominable submarine machines; they have already large numbers of excellent vessels, which we do not possess, and there is no doubt that we should soon obtain the best description of boat, which the existing knowledge on the subject can procure. The experiment would not cost much, for all the boats would be serviceable, although not in equal degrees. No doubt a them would be very strong feeling expressed by the builders at the time of the contract, each man thinking his own the best, but a committee of arbitration might be appointed which would be fair to all parties. The importance of torpedo boats has become too serious by endangering the very existence of our Navy, to be brushed up by theories on naval tactics; nor will the public be satisfied with the waste of many money in the construction of such absurdities as the Indefatigable. The Admiralty must face the matter, and, although it may go sorely against the grain, they will be compelled to take some steps towards remedying the many glaring defects, which, most undoubtedly do exist in our Navy, both as regards the small number and weakness of ironclads which are available, their inability as to speed to compete with foreign ships of the same class, and also our great deficiency in torpedo boats. The country has but already confidence in the administration of our Navy and dockyards, and unless some great improvement be made, it will be compelled to try whether it will not be possible to manage matters better, with some other system.

American Machinist, Sept. 20, 1884.

A Bogus Electric Light Company.

A New York electrical expert says he was recently employed by a capitalist to investigate the wonderful claims made for a new electric light on exhibition in a nearby city, to float which a stock company was being formed. The expert called at the electrical headquarters, and found in a single moderate-sized room thirty-six large arc lights pouring forth a bewildering blaze of light, the power for the dynamos used apparently being furnished by a small engine near at hand. On asking if "all that" came from that little engine, the electrical sharp said it did. The expert satisfied himself from an examination of the engine and dynamos that the thing was a physical impossibility, but couldn't lay his finger on the fraud in the face of the electrician's watchful observation. Calling again a day or two later, the expert brought a clever assistant, who managed to engage the "inventor" in an animated discussion, under cover of which he was able to make such an examination of the premises as led to the discovery of a lead pipe entering the premises in a wooded corner not seen without. Whipping out his knife, a few cuts showed wires inside the pipe. A search up and down the street brought to light the fact that five doors away a 100 horse-power engine and several large dynamos were busily engaged in producing the electricity, which proved to be made by the miniature engine and dynamos further down the street. The expert made his report, and the capitalist didn't buy any stock. If all the men who are asked to put money into wonderful electrical or combination companies should adopt a similar course of investigation before buying stock, it is safe to say there would be a good many corporations less in this country, and closer attention would perhaps be paid to the many modest claims of mechanics and inventors, who want to enlist capital and have only legitimate attractions to offer.

AN ELECTRICALLY LIGHTED TRAIN.

The London, Brighton, and South Coast Railway Company have three electrically lighted trains running on their lines, and a fourth is nearly ready to be put into service. It will be remem-

THE PROGRESS OF ELECTRIC LIGHTING.

YESTERDAY a deputation of electric lighting engineers waited on Mr. Chamberlain to confer with him on the modification of certain clauses in the Electric Lighting Act. Whether this interview will have much effect remains to be seen. We much doubt, however, that any change in the law can touch the core of the trouble. Electric lighting is at present in a very anomalous position. So far as the establishment of a house-to-house system of lighting is concerned, it makes no progress whatever. Indeed, the movement is rather in a retrograde direction, for the London, such as the Edison Company's in Holborn, which were established, have been closed. On the other hand, new works are being done in lighting individual buildings, such, for example, as the new Law Courts, Electric Palace in Victoria-street, and the Fleet Avenue Hotel in Holborn; while at no time has so much as lighting been done to docks, railway stations, iron works, &c. A great deal of incandescent lighting, too, is being done in cotton mills in a small way, the dynamo machines being driven by hands from the mill engine; and as we have seen, the question of large has narrowed itself to this.—Why cannot district lighting be established? Plenty of provisional orders have been obtained, districts have been mapped out, designs proposed, companies formed—these last on paper—but nothing has come of it all. On the one hand, it is argued that the Electric Lighting Act has not been severe simply fatal to the novelty it was supposed it would be better and cheaper; on other hand, it is stressed that clauses in the legislation has nothing to do with the matter, and that the great secret of non-adoption by the public lies in the fact that electric lighting cannot be made to pay. It is quite easy to see how both arguments are right; but the influence the one party or of the Electric Lighting Act may be wholly neglected if it can be shown that, even if the Act or no Act, electric lighting cannot be a commercial success. We fear that this is a fact, and that a great deal has yet to be done by way of cutting down expense before commercial success can be claimed for it. Edison is a very clever inventor, but it does not appear that he, more than any one else, can achieve impossibilities; and it is now fully understood that the system of lighting with which he identified is the most expensive ever in existence. We need not stop to say a word about the grace of the idea of incandescent lighting, but like most other beautiful things, it is frightfully costly. The method over which agitated men's minds a couple of years ago, brought to the knowledge of middle-class folk with ostentatious announcements in the daily papers, is now a mere matter of history. One of the very first things they found out was that light, not furniture, not dress-coats, and not papers, to say nothing of dadoes, and pictures, and the like, cost a tremendous lot of money. The appetite for luxurious and light had overlooked this little difficulty. Incandescent lighting must be cheapened, be cheaper, be cheaper, or it will die. Let us first prove that it is possible to be cheapened enough to be acceptable to the average house holder, legislation will not help it. Parliament may alter the Act as often as it pleases, but it will not make any one any more than it is now. Why incandescent lighting has not been a success we have already explained, and we will not repeat ourselves here. Suffice it to say that it has failed, and failed all along the line. It was to succeed in the city, but it has not done so. It was to succeed at the West End, and with Edison himself on the spot to advise, incandescent lighting has not begun to succeed. If it is to succeed at all. In 1882 Edison opened the First Pimlico illuminating district. He undertook to light an area with a little under one-fourth of a square mile, and the supply was found by the Edison Company, Limited, that in a month there were 12,540 lamps up, the number having gradually risen from 2222 lamps, with which the mode was first opened. The mains were all laid underground. Edison's own, so to speak, and he did "all" that he knew how to do to make the speculation a success. But the result, notwithstanding, was a disastrous failure. The gas has been disastrous. The cost of fitting up the district has been £200,000, and the actual receipts last year were £6000 in excess of the working expenses, about £16,000 a year. This means about 3 per cent. on the capital; but then no allowance is made for depreciation, and it does not seem much explanation to sharing with that a return of 3 per cent. in such an undertaking is to be considered a success. In fact, the profit, if there was any, was generally nominal. The average life of the lamp seems to have been 400 hours only, or about one-tenth of the durability claimed for Swan's lamp. Our contemporary, in the Stories, in dealing with the question, points out that about it is impossible that a 16-candle incandescent lamp can be made to last more than a 7th, per 16, with any commercial success. This be the case in London, then electric lighting must be a failure, nearly twice as much as gas—which it decidedly is not.

Are we to assume that this state of affairs is to last for ever? We venture to think not. In the first place, half as much energy had been expended on new inventions as has been spent to the incandescent system, the whole subject would stand to-day on a different footing. There are great possibilities to be seen in electric lighting, possibilities to be found out in the United States. The great fault in incandescent lighting, as we have said, is its variability, and that there seems to be no possible means of curing. Then, although, as a rule, the largest number ever up at one time was 12,540 lamps first only. The average during the year was 6000 lamps, or to the whole of the plant, we only about two hours. Suppose we compare the effect of this with a central electric station with that on a central gas-works. It is easy to appreciate what it involves. The gas-works run steadily day and night, the gas-holders form a reservoir, so to speak, and intercepting irregularities in demand. If the station is a steady falling off in the requirements of the public, the evening, for instance, then one or more retorts are cleaned; with the advent of long nights the retorts are charged; but the plant in action is always worked to the best advantage. The electric lighting station, on the other hand, has nothing to intercept or equalize fluctuations in demand, and a plant adequate to feed a couple of thousand lamps may have to be kept going to supply a few dozen. Let us suppose that all houses in a street are lighted. At midnight all the lights are out, save in one house, where a dancing party is being given, which does not break up till dawn. The whole of the plant provided to supply fifty houses has to be kept burning to light up one house. Nay, more. Lights at the station must keep at the bottom of a sick person all night. The of a few lamps burned in this way must be reckoned up in pounds per hour. Of course it may be urged that this need be got over. We do not deny that it can, but it has not yet been got over. The storage battery promised to make electric lighting by inconsistence a success, but it has not kept its promise, simply because there is no good storage battery in use. We say this with a full knowledge that there are storage batteries which have attained a fair measure of success, but they do not seem to satisfy electricians in general. We stated months ago in these pages that commercial success was not to be expected for incandescent electric lighting without the aid of storage batteries, and nothing has since happened to make us change our opinion. It is, we repeat, absolutely essential either so to construct a central establishment that variations in supply will not injuriously affect its flexible arrangements, or else to introduce between the consumers and the producers some regulator which will equalize the demand on engines and dynamos machines no matter what the fluctuations in the requirements of the public.

ELECTRIC LIGHTING AT MONTREAL.

THE absence of the incandescent electric light in the city of Montreal was commented on in the discussion which took place after the reading of Mr. Preece's paper on "Domestic Electric Lighting" at the meeting of the British Association. The great natural water power, with which several of the largest Canadian cities are so well provided, has not yet been taken advantage of, and should enable a general supply of electricity, both incandescent and arc, to be furnished at a rate that would be much cheaper than gas.

In accordance with most American cities, the streets are lit by electricity, and as the system adopted is one which has not been introduced into this country, we propose describing it. It is the Thomson-Houston dynamo machine, of the continuous current type, and approximately resembles the Brush in that it is wound to furnish a current of 2000 volts electro-motive force. The lamps being differential and worked in series with 10½ amperes current. In detail, the construction of the machine is peculiar to itself, and consists of a spherical armature made up of three coils of wire which are wound in the Siemens' form on the outside of a Gramme ring composed of soft wire. This armature is revolved between four pairs of two cup-shaped electro-magnets, these enclosing nearly the whole of the armature above the horizontal plane, and extending in a powerful magnetic field, which is concentrated where it should be utilized to give the best results. The three coils are connected together at one end of the armature, and the other ends are put through a hollow in the shaft until they come out at the end, where they are connected to the commutator which has only three segments. The electricity is led off by two pairs of brushes which are connected through and their position adjusted by means of suitable levers. They are worked by the automatic current regulator Fig. 3, which is shown in its place on the left side of Fig. 1. The regulator consists of a single pole electro-magnet with a peculiar shaped armature, which is a hinged bar of iron having a curved surface through which the pole of the electro-magnet enters; by this magnetic arrangement the pull of the magnet is the same at whatever distance the armature is from the pole. The current regulator is actuated by a controlling magnet, which, when in place in the line of the main circuit, immediately makes contact instantly alters the amount of current passing through the regulator, which consequently varies by the position of the brushes, and thus more or less cutting out the supplied field.

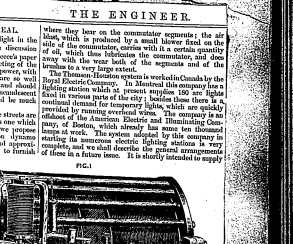

FIG. 1.

THE THOMSON-HOUSTON GENERATOR.

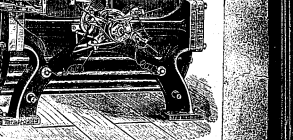

FIG. 2. FIG. 3.

AUTOMATIC CURRENT REGULATOR. CONTROLLER MAGNET.

The position which the pair of brushes occupy to each other, and the commutator bar long will be further determined by the stood by reference to the accompanying figures, Figs. 4 and 5, in which S is the commutator divided into segments K1, K2, and K3, Fig. 4, and 1, 2, 3, Fig. 5. From the brush-arm B, which is of brass, the brushes are in a normal position. Should line current become too great, the armature M will be attracted, and each pair of brushes will tend to separate; so that if all the lights be extinguished, the coils of the machine will be short-circuited, the magnetic field being almost entirely cut out.

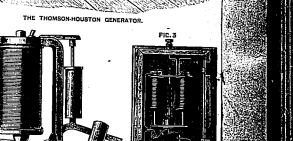

FIG. 4.

MODE OF CONNECTING BRUSHES AND REGULATOR.

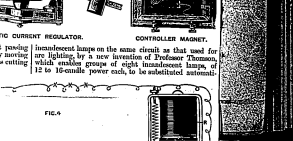

FIG. 5.

It will be seen that one great difficulty is overcome in the Thomson-Houston system, namely, the adjustment of brushes, which are often badly placed by unskilled attendants. Another ingenious arrangement in this system is the air-blast spark controller, which the inventor, Professor Elihu Thomson, claims to provide a complete solution of the problem of controlling the sparking or flashing liable to be so troublesome at the commutators of all dynamo machines. The invention consists in forcing a thin jet of air against the coils of the brushes [illegible] where they bear on the commutator segments; the air blast, which is produced by a small blower fixed on the side of the commutator, carries with it a certain quantity of oil, which thus lubricates the commutator, and does away with the wear both of the segments and of the brushes to a very large extent.

The Thomson-Houston system is worked in Canada by the Royal Electric Company. In Montreal this company has a lighting station which at present supplies 150 arc lights fixed in various parts of the city; besides these there is a continual demand for temporary lights, which are supplied as required by running overhead wires. The company is now offshoot of the American Electric and Illuminating Company, of Boston, which already has some ten thousand lamps at work. The system adopted by the company for starting the numerous electric lighting stations is very complete, and we shall describe the apparatus and arrangements of these in a future issue. It is shortly intended to supply incandescent lamps on the same circuit as that used for arc lighting, by a new invention of Professor Thomson, which is now undergoing trial. The lamps are of from 8 to 12 to 16-candle power each, to be substituted automati-

ELECTRIC LIGHTING AT THE ELECTRIC LIGHT.

As we stated last week, an influential deputation waited on the President of the Board of Trade on Thursday, the 25th inst. The deputation consisted of Lord Thurlow, chairman of the Anglo-American Brush Electric Light Corporation; Mr. Peter Brunswick, Q.C., Mr. Ewart, and Mr. Jacob Aiken, Mr. R. E. Crompton, Mr. Robert Hammond, Mr. Arthur Cooper, Sir Daniel Cooper, Mr. T. H. Cuthbit, Major Flood Page, Mr. F. Cousins-Javal, Dr. Farquharson, Mr. Lane, and others. The object of these gentlemen was to point out to Mr. Chamberlain the expensive and inconvenient character of the Electric Lighting Act. One of these gentlemen—we have not time to say which—drew attention to the property of an electric lighting company at the end of twenty-one years, and pointed out that the power conferred upon the local authorities to supply electricity in any one who may see fit to demand it, involved the necessity of a complete system of mains in which these clauses militate against the prosperity of electric lighting companies. Mr. Chamberlain, it is said, gave Sir Frederick Bramwell and Mr. Crompton. Dealing with Mr. Ribton's case, the first-named gentleman said that under that clause within twenty-one years the local authorities would have the option of the compulsory purchase of the undertaking, and they were to do it on certain terms. They were not to pay anything in respect of compulsory purchase, or goodwill, or profits. Undertakers would be left to be paid for the value of all such lands, buildings, works, materials, and plant of such undertakers as might be used by the local authority for the purposes of their undertaking within such jurisdiction, such value to be, in case of difference, determined by arbitration. The period was twenty-one years, and the matter of those terms was, that all the revenue efforts to get the electric light taken up so as to pay working expenses; and it did appear to him that it was impossible to induce capital to come into such undertaking, after all these years of struggle had been gone through, if the local authority could step in and purchase at a price less than a fair one. He did say that at the end of ten years a company might have to be found further by the expiration of the period, and under the circumstances no one would subscribe capital at that time with the certainty to getting capital invested in such undertakings.

Mr. Crompton confined his attention to the clause dealing with compulsory supply, and pointed out that the Corporation of London had declined to show how this portion of the Act would be worked. In the case of Brighton, they were only compelled to maintain over a given area without any regard to the possible future to be got out of them, so that it was the best system of laying mains to adopt. We had, said Mr. Crompton, practical experience in the fixing and working of detached sets of plant, but that these could not be compared with the case of a district like the city, at all events, few or no public companies had been formed in London, and he thought that prevented us from increasing our stock of knowledge in the one respect which would have to be got out of them, so that the supply of electricity might be carried on in a satisfactory manner. There have been a number of failures in connection with the parallel working of main lying tried in America, and the data obtained have very considerably added to the knowledge of ascertaining what is really the system which best answered the purpose. Another difficulty in ascertaining what was the best system was the difficulty in ascertaining what was the cost of working. Briefly, the two great objections to the laying down of mains for a district like that of the City of London were these:—That it would commit us to a large capital expenditure on a system which was probably mechanically imperfect system; whereas at the

[illegible] every instance certain sums; in pursuance of these they make certain suggestions for amendments. Nothing has been done in connection with the Committee's suggestions, but there may be some chance of practical results now that the Committee has got the Board of Trade to authorize a further enquiry. There can be no question that the system similar to that which prevails in the maintenance of the street was applied by any private company they would be faced with the same difficulty in ascertaining the cost of working. Briefly, the two great objections to the laying down of mains for a district like that of the City of London were these:—That it would commit us to a large capital expenditure on a system which was probably mechanically imperfect system; whereas at the

[illegible] Committee, and the Committee in the following passage hit the blot on the whole matter. They say:—"The great objection which takes place in the dockyards under the heads of repairs and refits is stated in evidence to be due in a great measure to the stringent examination entailed upon the professional officers by the instructions; which were rendered much more rigid in consequence of the circumstances attending the loss of the troop-transport Megaera, and partly to the nature of the supervision exercised by the captain of the steam reserve and his staff." It is well known that this passage does not exaggerate the evil influences which the Megaera inquisition began in the personnel administration. The members of that Commission were well meaning men, but they were unfamiliar with technical questions, and their treatment of the dockyard officers whom they held responsible for the condition in which the Megaera was sent to sea was such as to discourage for future any attempts to economize in the repairs or re-fits of ships. Every officer bearing the strictures of the Commission in mind, would, in the future devote his first place to make himself quite safe, and the "forms" which the officer now has to sign up the completion of a ship's repairs have been made so binding and searching, that without taking a ship practically to pieces it is impossible to satisfy oneself that

THE BOARD OF TRADE AND ELECTRIC LIGHTING.

TO THE EDITOR OF ENGINEERING.

SIR,—Mr. Chamberlain's reply to the deputation of the 29th inst., encourages discussion upon the terms of the optional purchase under sec. 27 of the Electric Lighting Act, 1882. That sets forth a option means a foregone conclusion. To take the discussion out of the region of pure speculation, I shall take a somewhat parallel case in actual experience.

Thirty years ago, the financial practicability of railway enterprise in India was rarely hypothetical. Experimental railways had been constructed, and traffic had been made. So early as 1845, the East Indian Railway Company had been incorporated by Act of the Imperial Parliament, and an experimental line was soon afterwards made by aid of a subvention from Government, then that of the East India Company. The public, however, were not easily to be convinced that railway works could be successfully undertaken in India, and the financial and physical conditions of the country, and the traffic still more to the point, the problem still awaited solution. Under these circumstances the usual rate of the accumulation to be provided. The Indian Government were desirous of attracting private capital to the enterprise, but for this it was necessary not only to confer a monopoly of powers, but to give a guarantee of interest. In consenting to this they did not sacrifice the Government property. In assenting to this terms were sufficiently conditional so as to be fair and not repellent to investors.

The final contract of the Indian Government with the East Indian Railway Company was made in 1854. The Government guaranteed a minimum dividend of 4*l*. per cent.; except in the event that amount in any year were to be shared, one-half of the surplus profits going to the Government for their outlay on the guarantee, and the other half to increase the dividend. And there was a further provision of purchase by the Government, to be exercised by notice to be given within six months after the expiration of

twenty-five years, or within six months after the expiration of each fifty years. The purchase money to be "a sum equal to the full amount of the cost of all the shares and capital stock in the company existing at the expiration of the twenty-five years immediately preceding the expiration of the said period of twenty-five years, or the said period of fifty years, as the case might be."

The Indian Railway Act, which settled in 1854, were the basis of the great railroad system of the East Indian Railway, and it may be said of the railway system in India. The identical terms were embodied in the Government contracts with all the railway companies in the earlier undertakings in India.

To return to the East Indian Railway Company. The Government guaranteed the strength of the contract of 1854; and the undertaking carried out. After some years the profits were found to have exceeded the guaranteed amount, so that, after dividing the surplus with the Government according to the arrangement, the dividend of 4, 5, or even 7 per cent., over the guaranteed 5 per cent., was paid to the shareholder. The stock improved steadily, and at about 25 years from its issue, for exercising the option, stood at about 25 per cent. premium. At this time a necessary result was caused by the option of the Government calling attention to the existence of the option. It was then discovered had time to look into the matter, the terms of the clause were found to have been adjusted with such fairness and forethought, that prices quickly reversed the usual course of events, and, when the Government (the Secretary of State under the powers of the Act of 1858) declined to exercise the option, the stock fell to par in the market was a depressed by the Government to have further to secure the success of the loan financial operation required for carrying out the purchase money. The new arrangement (3 and 4 Victoria) by an Act of the Imperial Parliament, 1840; and the 5th, (sp. cent.) took effect from January 1, 1849; and the Government acquired at the price of 25 per cent. premium—perhaps as an expenditure including all over the original cost—an undertaking of proved and increasing value, with the accumulated trusts of extraordinary profits, and financial management, in every respect, a remunerative purchase. Indeed, so important was the success attributed to the private management, that under the new arrangement, the company retains a certain interest in the control of the undertaking, which continues to be carried on by the directors of the company on behalf of the Government.

A similar result has been lately exercised in the case of the Eastern Bengal Railway, by notice given in 1880, and under an arrangement confirmed by an Act of the Imperial Parliament in 1884. In some other cases the Government have not found it expedient to exercise the option; and perhaps there are cases, but these are exceptional, in which it is never likely to be exercised. Even where the railway has been, financially, a comparative failure, the terms of the option have in practice been a fair compensation for the losses on the investors hard creation. Such a case, however, only illustrates the fairness of the terms of the option. Under the present Government has required the undertakings which have proved successful.

In the case of electric lighting there is no question of experience. All that is asked is that undertakers for lighting on a large scale shall have the necessary powers, and the necessary guarantees to make the enterprise safely. In the case of the Indian railways, the question was not only the consideration for the pecuniary guarantee. The analogy does not justify any condition of an option in the case of electric lighting. But assuming that the principle of clause 27 is unalterable, and the option of purchase a *sine qua non*, the history of Indian railways would suggest a much longer period up to and for some years beyond the actual exercise of the option, in a precedent showing the terms on which the option would be exercised considered not only with the consideration of private enterprise, but also (what is a point of some importance with stockholders in the stock value of the property affected.

Look at the Indian Government, in new railway undertakings, can and does impose harder terms, is only an illusion. The Government can impose new and unfamiliar terms, and no undertaking on which the profits can be estimated by untried experience. This difference is one of degrees of the supposed analogy between electric lighting

and gas and water supply. There is the further difference in the case of water companies, that their concessions involve not only the right to supply so called, but the exclusive appropriation of natural resources. False and misapplied analogies, indeed, seem to be the whole existing legislation upon electric lighting.

I am, Sir, yours faithfully,

13, Old-square, Lincoln's Inn, November 24, 1884. H. CAMPBELL.

EXTENSIVE USE OF THE ELECTRIC LIGHT ON THE CONTINENT.—A scheme is on foot, says *Nature*, having been approved by the Municipal Council of Paris, for lighting with electricity the quarters of the Perfecture of the Seine, in the Tuileries. It is the work of M. Cernescon, and comprises lighting the Salle des Séances with eighty Swan lamps (in place of eighty Carcel lamps), and six Siemens' arc lamps; lighting the library with forty-eight Maxim incandescent lamps (on the present lustres); another room with twenty-four Edison incandescent lamps; another with twenty Swan lamps; the Salle des Pas Perdus with two Werdermann arc lamps, and two Siemens' lamps, and a staircase with eight Swan lamps. The whole will require an outlay of 75,000 f. The horse-power necessary is 42, and while the idea of obtaining this from the Seine has been considered, it has been decided to set up a gas-engine in the Court of the Tuileries. A portion of the motive force is to be employed for electrically ringing the sentinels, and other uses. The Paris-Lyon-Méditerranée Company have illuminated their Paris terminus with fifty-four electric lamps on Jablochkoff's system, and that of Mazarilles with seventeen of the same lamps. Some others which is to be increased by eighteen. The French Northern Company has tried, with success, the of the electric light in the long of locomotives. The Paris Municipality have decided on trying the electric light for the Theatre Royal.

A CHURCH LIGHTED BY ELECTRICITY.—The Rev. Canon Cadogan Churton, of St. John, built by the Marquis of Bute, at Old Cumnock, Ayrshire, has recently been fitted throughout with electric light, under the personal superintendence of Mr. Wm. Massey, Twyford, electrical engineer at the royal palaces. There are in all about 70 glow lamps of 20 candles each, and the effect is excellent. The architectural features of the church have been carefully studied and the lamps arranged with a due regard to the religious character of the building. The current is supplied to the lamps by means of a dynamo and steam engine placed in a small house hidden among the trees of the churchyard, where it is also intended to produce electricity for working the organ bellows.

THE ELECTRIC RAILWAY AT WEST BRIGHTON, CONEY ISLAND.—The only electric railway for commercial purposes in America now in successful operation is that on the new iron pier at West Brighton, Coney Island. Extensive experiments have been conducted by Messrs. Daft, Field, and Ellison, and a very thorough practical test of the Daft system was also made on an existing steam railway last November, at Saratoga Springs, the result of which is that the new railway at Coney Island is worked by the Daft system. It extends for 760 feet along the west side of the West Brighton pier. The track is of 2-foot gauge, the rails being of the T pattern, 20 feet in length, 3 lb. to the foot. These are laid on strips of wood, and are firmly bolted to the pier planking. No attempt is made at insulation, none being needed, as on the wetted wood the leakage would be small even if not compelled. The dynamo is situated, as at Saratoga, at the end of the pier. It is a 6-horse-power current dynamo of Professor Daft's invention, the E.M.F. is extremely low. The intensity of the current varies with the external resistance, and upon this depends the speed of the motor. The weight of the latter is about 600 lb., and its normal speed 1,100. It is driven by an 8-horse-power vertical engine with belts to correspond, manufactured by the New York Safety Steam Power Co. The speed of the engine being 250, direct belting was possible. Two cars are provided for the conveyance of passengers, each 12 feet 2 inches long and 32 inches wide, weighing about 600 lb., and accommodating twenty persons, six on each side, sitting back to back, making a normal load of forty persons. As many as fifty people have carried at one time, a total weight of about four tons. The weight of the motor is about 1,200 lb., and its maximum speed from twelve to fifteen miles per hour, although this is obviously limited on so short a track. The author had an opportunity of practically testing the merits of the Daft system. In the transmission of the power, electrical purposes its advantages have already been demonstrated. No doubt this railway will be the forerunner of many of its kind in America.

REFLECTED ELECTRIC LIGHT.—The experiments which have been conducted on board the *Sultan* at Portsmouth, with a view of ascertaining whether the electric search lights in men-of-war could be protected from the guns of torpedo boats by the adoption of reflected light, under cover, have been concluded. The official trial was witnessed by officers from the Admiralty and the War Department, as well as the local Torpedo School. Four different sets of lenses were tested for the purpose of comparing the intensity of the electric beam being measured by a Bunsen's photometer at first and at 2 cables' length. The apparatus used were a 24-inch search-light lens on ordinary principles, an Ader illuminated their Paris terminus with fifty-four electric lamps on Jablochkoff's system, and that of Mazarilles with seventeen of the same lamps. The force which is to be of locomotives. The Paris Municipality have decided on trying the electric light for the Theatre Royal.

ELECTRIC LIGHTING.

(22/12/84.)—Years leading article of 29th Nov., on "Electric Lighting," must have been read by many others besides myself with much interest; but I should like to point out an omission which inspires greatly its usefulness. I am sure there are many who are desirous of fitting up just a few installations of electric lighting in their houses or business as well as houses; but the difficulty of choosing between dynamos and lamps are the bar? There seem to be plenty of good machines in the market—Which make is the best, combined with cheapness of first cost, and economy in working, both as regards the lamps and the motive power?

You pertinently remark that considerable economy may be effected "by using the same engine to drive the dynamo, and the dropped (not necessarily horizontal) lamp." You proceed to say that there are machines which are superior in several ways to some of the unpatented cheap ones. Just so, Mr. Editor, and I think your readers would welcome a list as to which they are.

My special reason for writing is this: Ina part of my works I have to use gas from 6 a.m. to 9 a.m., all the year round, about 25 lights altogether. I find the atmosphere deteriorated very much, besides there being considerable risk of fire from the naked lights. I am therefore wishful to substitute them by electrical lamps. I have plenty of surplus power available, and I should be extremely obliging nature, so that I shall save the expense of having to purchase the motive power. As I mentioned before, however, I am deterred by the difficulty of knowing whose dynamos and lamps to choose, and I leave it to independent authority to apply to your here to assist me. If I go to an electrical engineer, of course he will advise me to adopt that company's or maker's machine for whom he acts as agent. Some machines are supposed to run more lights in proportion to their size, and the question arises, Is it better to have a large machine some load after being at work a few hours, and some claim to cost very little for repairs. I have closely watched the progress of electric lighting since it entered upon a stage of practical usefulness, and yet I seem as far as ever from being able to decide whose system to adopt, as being the best and cheapest. Perhaps I am over-cautious, but I dislike mistakes, although I am not afraid; only I venture to think you or they will be rendering others, as well as myself, a substantial benefit, if you append to you, with confidence, as having been a reader of your most admirable journal for many years, I have noticed that help is nearly always given to those who require it, and I therefore trust you will not leave my colleague his difficulties. In conclusion, I should say the system which I adopt must not require a skilled electrical attendant. And also, if it is a success, I should probably extend it throughout the whole of my works, having about 200 lights, which, however, are only required from dusk till 6 p.m., and 6 a.m. till daylight.

H. D. C.

Iron — Augs. 8, 1884.

TRAIN LIGHTING BY ELECTRICITY.

Those who have watched the course of events in respect of railway train lighting by electricity will be aware that several systems have been tried for this purpose, as reported in our columns, and we believe some of them are still under trial. Two systems mainly have been experimented with, variations in detail being introduced as suggested either by inventors or by railway managers. One of these is the secondary or storage battery, of which a number are placed in the train and the light distributed from them. Another system is that of primary batteries, of which we have heard little or nothing of late. Another method of electrically lighting a train is to fit up a dynamo in it and run the lights direct off it, trusting for the motive power needed for the dynamo to the locomotive or to a separate engine fed from the locomotive boiler. This is unsatisfactory. The light cannot be supplied to the train unless when the engine is attached to the carriages, and as this rarely happens until a few moments before the actual starting of a train from the terminus, the carriages are consequently left in darkness at a time when they require light most. The supply is irregular, and there is the necessity for a separate attendant, whose wages do not stand the plan as too costly. We do not begin that a system has been tried on which a separate engine and boiler were used, but we are not aware that any practical progress has been made in this direction. The system of train lighting by electricity by means of accumulators has been in use on the Brighton Railway for the past two years, having been applied to the Pullman train, as reported by us at the time. It has, however, been found to be slow, inconvenient, and expensive. In the first place, a steam engine is required for the dynamo to charge the cells. Next, there is the rental premises and the wages of an attendant. Then there is the cost of carrying to and from the train the cells when charged and discharged, and the injury occasioned to them therefrom, for while it is admitted that the travelling in the train does not appear to affect the cells perfectly, it is beyond dispute that repeatedly shifting the position of cells must be most undesirable.

These drawbacks long since presented themselves to the mind of Mr. Stroudley, the locomotive superintendent of the Brighton railway, but he saw that both the economic and the direct dynamo system possessed advantages which, if the two systems could be blended, might produce satisfactory results. In conjunction, therefore, with Mr. Houghton, Mr. Stroudley has devised and perfected such a combined system, and it has been carefully and successfully tried on the Brighton line. The system — which is being introduced by the Railway Electrical Contracting Company, Limited, 4, Great Winchester Street, London—comprises the utilisation of power from the axle of the engine by an arrangement of belting and shafting on to the spindle of the dynamo. The working apparatus consists of a dynamo machine of the necessary electro-motive force to give a sufficiently current never to absorb the accumulator (if when no light is required), and to add to such output the requisite supply of current when the whole of the lamps are on. Beyond this, and most automatically excites the field magnets of the dynamo prior to the closing of the circuit, shuts it out of the circuit until the speed of the train is such as to create an E.M.F. in the dynamo sufficient to charge the cells, or when the speed is so reduced that the E.M.F. of the dynamo is less than that of the cells, then to cut the dynamo out of the circuit, as otherwise the cells would play back on to the dynamo. The apparatus also prevents any excess of current being generated in the dynamo when the train is running at an abnormally great speed. The accumulator or store being always kept full or well filled, a light can therefore be obtained while the dynamo is not at work, and without the necessity of the engine being attached to the train. The only attention that is required is at the terminus, when the brushes of the dynamo have to be looked at[illegible] to see that they have preserved their proper angle. During the day-time, when the light is only needed when passing through a tunnel, the guard can, by turning the handle or lever of a simple switch, put the light on, and by reversing the lever it can be shut off. At night, when a constant light is wanted, the switch is kept on continuously, and the accumulator and dynamo working in conjunction supply the current. Another important feature of the apparatus is that it is automatically reversible, and consequently works no matter in which direction the train is going.

The installation itself consists of a specially modified form of Brush dynamo, a storage battery consisting of twenty of the Electrical Power Storage Company's cells, and the automatic apparatus, the whole being fitted in a portion of the guard's brake van. The connections between the carriages are so constructed that they can easily be uncoupled, and in slip carriages will be so automatically. Two trains on the Brighton line have been fitted up on this system, a local and an express train. The local train commenced running on November 29, 1883, and has worked without cessation ever since. During the foggy weather the light was often burning from two or three o'clock in the afternoon until midnight, and we are informed that there has never been a failure at any time. The express train which has been now fitted up is so arranged that there are two lights to each compartment, to prevent the possibility of a compartment being left in the dark owing to the breakage of a lamp. The present lamp glasses and holes in the roof of the carriage are also utilised, and the electric lamps may be removed and replaced by a man on the roof quite readily. Altogether the plan appears to be a success, and to present the best solution to the question of train lighting by electricity that has yet been advanced.

Dundee — August 21, 1882.

ELECTRIC LIGHTING FOR STEAMSHIPS.

At the first meeting of the session of the Institution of Civil Engineers, on November 11, Mr. J. W. Barzalgette, C.B., president, in the chair, a paper was read on "Electric Lighting for Steamships," by Mr. Andrew Jamieson, C.E., F.R.S.E. The author commenced with the statement, although it was not more than three years since the first application of incandescence electric lighting to the general illumination of steamships, many reasons had arisen which had been as universally adopted as the advantages accruing therefrom had been as universally recognised. The daily cleaning and replenishing of lamps, as well as the keeping in store of highly inflammable oils, paraffin, or candles, could be a greater extent be dispensed with. 4. The expense of maintenance was not much in excess of that of the other methods of illumination (in some cases less), whilst the space occupied by the plant was not great, and its position near at, or in the engine-room caused no annoyance to passengers.

In fitting the dynamo which furnished the electricity for feeding the incandescence lamps had to be driven at a sufficiently high velocity, either the ship's main engine, or, as in the donkey nor winch-engines, were suitable for the purpose. The dynamo must have an engine for itself. In most cases, necessary to place this special engine and the dynamo in such a position that the man on watch at the main engines could, with a minimum of trouble, attend to the working of the electric plant. This position, therefore, was naturally somewhere near the starboard engine, and as close to the ship's frame, so that any excessive vibration and noise might be avoided. Frequently a second dynamo would be provided, either immediately beside the main starting platform or opposite to the thrust block, or, in cases where screw-shaft tunnel does not exist, in large installations would it pay to have on board an electrician to attend to the working of the dynamos, for, as a rule, and in most cases a convenient and cool position was generally selected for the dynamo, in the same compartment as the main engines or near the refrigerating machinery, if such should be on board, so that one man might attend to the whole of the machinery. Where practicable, the axes of dynamos with large, heavy armatures should be placed fore and aft, to obviate as much as possible the effects of gyrostatic action, since the engines would then be working with the greatest advantage. The author here gave Sir William Thomson's formula and example, to show the pressure produced on the dynamo bearings, under different circumstances, by a gyrostatic action.

In selecting a dynamo, it was necessary to determine its suitability for the fulfilled certain requirements:—(1) It must develop electromotive force suitable for a certain lamp when driven at a certain definite speed. (2) must be self-regulating; that was, the electromotive force generated by the machine must remain constant to within 2 per cent., whether working one lamp or more, or the full number of lamps. (3) The machine must be of a light build as electromotive force to the number of lamps was reduced. (5) There must be no sensible sparks at the commutator-brushes. (6) When running light, or with less than the full number of lamps, there must be no undue heating of the armature. (7) The conductivity of the copper wire with which it was covered must not be less than 95 per cent. of pure copper. (8) The insulation-resistance of the armature and electro-magnets should not be less than 10,000 ohms per volt generated at the required speed. The dynamo should be tested mechanically and electrically, and then, when placed on board ship, and afterwards, when fixed in position, by a final trial of not less than six hours' duration, with its own engine, and with all the lamps in circuit. There was considerable discord of opinion regarding the limit of speed of a dynamo on board ship. As a consequence of the general desire for low speeds, most of the best forms of dynamos, the Siemens, the Edison, the Edison-Hopkinson, the Victoria, the Gerard-Siemens, and the Brush-Rickmeyer, had been specially modified for ship use, so as to produce the required electromotive force and current. At speeds varying from four hundred to six hundred and fifty revolutions per minute, the number of failures of an installation of any kind attended so much upon the engine as upon the dynamo, and every care should be taken to procure one that needed the minimum of attention, and was not likely to break down. The engine should be capable of driving the dynamo from Glasgow to Australia and back, without a hitch and without overheating. The demand for small engines specially for these driving direct, had led to the production of a class of machinery, many of which it is unfortunately to be[illegible] frequently necessary that the engine should be capable of driving the dynamo when supplied with steam either from the main boilers or from the donkey-boilers, so that the electric light might be kept in operation when the ship was in port. The author here referred to various suitable engines, and then to the size of the engine best suited for driving the dynamo. One of the most important attributes to the engine was its governor. It should be sufficiently sensitive to enable it to keep the engine within 5 per cent. of its normal speed, with a load varying 50 per cent., and a boiler-pressure varying 10 lbs. per square inch. No one mechanical governor, and consequently a good electrical governor, which would act automatically upon the throttle-valve, to perform unintermittent work with the load, or when required to do so, and leave the valve in the position until a change was made either in the load or in the steam-pressure, was greatly to be desired. The author showed how this difficulty had been solved by means of his electrical governor.

Then were detailed the different methods of driving dynamos on board ship by belts, ropes, gearing, direct from fast-speed engines, such as Rothenfield's and Worthington's steam-pumps, and from slow-speed engines, by various applications or methods of fitting leading wires into vessels, including a method which, in some cases in place of the steamship *Arabistan* and the steamship *Arcadia*, and gave a practical rule which he had been in the habit of using for the dimensions of such wires. Insulation-resistance was too often neglected by electric-light engineers. Amongst submarine telegraph engineers it was considered of vital importance to obtain high insulation resistances with the most rigid accuracy, not only during the manufacture of a cable, but during its submersion, and after it had been laid; whereas, in the case of electric lighting, those charged with the fitting up of an installation gave little thought of, or even knew how to take, insulation tests, either of the dynamo or of the leading wires. It was far from right to allow leads to be run up like bell-wires, without the slightest knowledge as to whether a screw or a knife had crept in; and all engineers should insist upon rigid inspection, as well as thorough and searching tests, before an installation was passed. The insulation-resistance standard need not be nearly so high as in the case of submarine cables; but, nevertheless, it did require to be several hundred times more than the copper resistance, otherwise there would soon develop and short circuiting occur, under the combined influence of the electromotive force and damp or wet. The dielectric should, therefore, in addition to having good insulating properties, be highly water-tight, and as little affected as possible to be affected by atmospheric changes. The author then gave a description of what he had found to be the best form of switches, fusible plugs, lamp-holders, fasteners, and glasses. Finally, he directed attention to the powerful search lights used on board men-of-war, and to the more sophisticated use of lighting for salvage and fishing purposes. The paper was illustrated by a large number of diagrams.

The Engineer — May 13, 1882.
2 York Buildings, Adelphi, W.C.

THE ELECTRIC LIGHT.

An Exhibition Last Night that Reveals the People of York With Admiration.

Our people have treated last night with the grandest electric light exhibition ever shown in York. The Overland Electric Light Company, who are introducing the Edison incandescent light, gave an exhibition of their powerful illuminant last night from THE AGE office, which was satisfactory in every particular. This was the first exhibition ever given in York with lamps arranged in groups upon the gas fixtures and hand lamps. The light is really powerful and steady, and in such a treat and as superior to gas as to make that illuminant look very sick and dull.

Crowds of people visited THE AGE office where the dynamo was located, to witness the light and workings of the wonderful machine. Crowds of spectators were also at the Morris drug store and Hoffman's clothing store, and went into ecstacy over the brilliant scene there presented. The exhibition last night was given at a disadvantage, as our press room and engine house is so crowded with machinery as to give but little room for the manipulation of the dynamo and attachments. The pulleys on the shaft for driving the dynamo were not sufficiently large to give the requisite speed required, and the engine had to be run at a very high rate of speed, making over 200 revolutions per minute, which used up steam very fast. Notwithstanding the hurried trial and the imperfect arrangements made, it resulted most satisfactorily, and only one stop was made in the three and a-half hours run. An engine running at such a high rate of speed is very likely to encounter hot boxes and journals, but there was no difficulty of this kind last night, and the whole machinery, engine and dynamo, behaved admirably.

The dynamo and exhibition is under the superintendence of Mr. Joseph Gunther, a thoroughly practical electrician. Another exhibition will be given to-night at the same places as last night.

Now that our people have seen the light, and are satisfied that it is better, safer, cleaner and cheaper than gas, the question is, are they ready to encourage the company in going ahead with and making a plant large enough to supply every store, and private residence in town? If sufficient business is guaranteed the company will be ready in thirty days to furnish a plant that will put you in a light that puts out the fame of gas. Turn it off or on at will, without the use of a match—a light from which there is no danger. Turn for it in any other way. We hope our people will encourage the company, which is a local one, and composed of citizens of York. The price will be as cheap as gas, and the service much better.

IRON.

LONDON, FRIDAY, AUGUST 1, 1884.

THE ELECTRIC LIGHT FOR AMBULANCE WORK.

IT is hardly necessary for us to point out that army ambulance work presents a high degree of perfection, and that the eminent humanity on the battlefield is well served by those who are attached to the corps or are connected with the army medical department. But there are circumstances in which the best intentions fail, and the most resolute endeavours are sometimes frustrated from a cause at present entirely beyond control, namely, the want of an efficient light. We refer here to that part of ambulance work which relates to the search for the wounded on the battlefield at nightfall after an engagement. Now, it is a matter of fact that in a driving rain or a heavy wind the field lanterns are frequently extinguished, so that the work of humanity has to be carried on under almost prohibitory conditions. Even if the rain or wind were quite stopped, in this respect electricity now steps in and promises to render invaluable aid in rendering the necessities of the wounded to be efficiently attended to on the field of battle. In darkness such as that which enveloped the battlefield of Sedan, and last year afforded the opportunity of demonstrating for the first time the use to which the electric light might be turned in enabling the necessities of the wounded to be attended to on a field of action at night time. The Viennese Volunteer Society for Aiding Life in Time of Warwill on February 20 next, have organised a demonstration for putting this application of the electric light to practical test. The demonstration was given with an electric light waggon, as constructed for military purposes in France by Messrs. Sautter, Lemonier & Co., of Paris. The French army and navy have long possessed thirty of these electric light waggons for use in the defence of their fortresses and magazines, and a certain number of similar electric light waggons, though of a different pattern, is employed in the military equipment of the German army. The Vienna demonstration took place in October 1883, and proved a thoroughly successful one. The night was foggy, but the light was found to be sufficient, in spite of the darkness and fog, for everything to be done by the medical staff and transport departments that was needed. The experiments were organised by Baron Mundy, to whom it has since occurred that the Health Exhibition might be made the occasion for introducing the electric light waggon in England, and more especially for making known its applicability to the purposes to which we have referred. On behalf, therefore, of the Viennese Volunteer Society for Saving Life, Baron Mundy took the necessary steps for composing his commendable scheme, and with the active co-operation and assistance of Mr. John Furley, a waggon was sent from Paris, the necessary fuel was also sent over for the purpose, and for exhibiting the light and its application in England, being provided by the National Society for Aid to Sick and Wounded in War.

Messrs. Sautter, Lemonier's electric light waggon consists of a wrought iron travelling carriage upon which is fitted a Field Artillery Motherhood three-cylinder engine of 3 horse-power is also mounted upon the carriage, together with a Gramme dynamo-machine, driven direct from the engine. The arc lamp is carried on the waggon, but is removable for use at any desired point, the practice being to operate at a distance from the waggon. The light from the carbons is not thrown direct on to the field, but is reabsorbed in a small concave reflector on whence it is reflected on to a larger one, the rays from which are thrown forward on to the object to be illuminated in a concentrated form, and portions comparatively limited from a circle of 300 yards in diameter. It is this form of light that is used for examining and bandaging the wounded, but for making the search the light is diffused over an area about three times as large by means of a lens which is hinged to the lamp and in fact forms its door. In order to give a practical demonstration of this light in England it was rightly thought that Aldershot presented the best possible facilities for the purpose. The authorities were, therefore, communicated with, and the lieutenant-general commanding Highness the Field Marshal Commanding-in-Chief, sanctioned and ordered through the Director-General, the Deputy Army Hospital Corps, Aldershot, a thorough trial of the apparatus with reference to its fitness for the purposes of military surgery. The demonstration of July 24, Baron Mundy personally superintending the working of the light. Surgeon H. T. O. Cross, A.M.D., was detailed to direct the tents and to report upon the demonstration by Surgeon F. B. Conolly, A.M.D., and Woolhouse and Beeson took charge of the experiments. A number of guests were invited to dine with the officers of the Medical Department, and afterwards to witness the demonstrations. Among these present were General Mackinnon, C.B., Sir Hugh Low, Dr. Crawford (Director-General of the Army Medical Department), Dr. Farquharson, M.P., A.M.D., Professor Longmore, C.B., Mr. Lieutenant Maclure, Commissary-General Major-General de Lint (the Russian military Inglis Irvine, and H. Gilmore, of the Peninsular Society.

We have said that Aldershot offers for such a demonstration, and this not on the presence of the troops and of the army department, but to the formation of the of the northern side of a valley stands the the moveable field hospital, consisting of up for the various purposes connected with ment of the wounded. About a third of ward of the field hospital was the dressing about a quarter of a mile to the south and down in the valley was the ambulance From this point the ground rises to the forming what is known as Rodan Hill, constituted the field of the imaginary electric light station was on the bottom of valley, the distance between the light's of the hill being nearly a mile. The volume is of from 2,000 to 3,500 candle power, of illumination is from 2,000 to 3,000 candle power, the application of wagon in searching for, succouring, and 100 men acting as wounded from the dressing station on the night after a sup by a hearty colonial meal at 8.30 p.m., with nude, mountain, and wheeled transport. The demonstration commenced at 9.30 p.m., the night being very dark but starry, with wind, and occasional very frightening to the men. The first column marched out from the field hospital, which was supposed to be established about six miles from Rodan Hill, where the imaginary action had just taken place. At this point we have previously pointed out, which was assumed to be about two miles from Rodan Hill, a dressing station was detached from the column. The column then proceeded to the front, and the mile (assumed) of the battle-field, where the collecting station was formed with the ambulance waggons of the first line. From this station the bearers advanced to the field with litters to search for the wounded. A large volume of light from the electric lamp naturally aided the bearers, not only in their search for the wounded, but in applying temporary dressings to the imaginary wounds. The nature of the wounds had been easily ascertained had they existed. Beyond this the conveyance of the wounded would have required higher surgical skill to have been brought to bear on the more serious cases, and present ease of necessary. The work was very easily performed, as the investigation of the numerous little groups dotted over the hill-side was made. It would be, moreover, that the men were well up to their work in applying the temporary dressings to the various cases of assumed burns, hæmorrhages, fractures, and limbs coming in the later stages of action and bandages. The passive and helpless attitudes assumed by the supposed wounded as they were being bandaged with white linen, and also whilst under transport, gave a strong semblance of reality to the scene, the illusion only being dispelled by the joke of a comrade as he finished his work. From the battle-field the wounded were conveyed down to the collecting station, some being lifted, while the transport out of the more seriously wounded was effected by means of litters, cacolets, stretchers, and improvised methods. The cacolet is an arrangement consisting of a seat on each side of a horse in which such are able to sit are placed and stepped on to after the fashion of children in swings. Others placed in stretchers were carried full length on either side of a mule or conveyed upon a litter. At the collecting station the ambulances were loaded and carried the wounded to the dressing station where the necessary operations were supposed to be performed and more elaborate dressings applied. Considerable pleasure existed between the collecting station and the battle-field round the whole of the hundred wounded men had been brought in. From the dressing station

Progressive Age - Jan. - 1884

DO EXAGGERATIONS PAY?

The following from the *Public Ledger* of this city contains a lesson that it would be well for more than one journal to take to heart. It says:

A technical paper commenting upon the exaggerated stories of dangers lurking in conductors for electric light says: "Electricity, always a subtle and mysterious agent, suddenly became in the eyes of the people a novel mystery and bug-bear. It is for the interest of all engaged in dealing with electrical energies to endeavor to subdue this needless alarm." Exactly so, but the best method of allaying needless alarm is to tell the exact truth. The practice heretofore has been to meet exaggerations with sweeping denials, plainly false in themselves. It is the truth alone that is needed to allay such apprehensions as should not be felt. Just so long as electric-light companies and their representatives declare that there is no danger in naked wires carrying currents capable of overcoming the resistance of as many as forty arc-lights, they may expect to be met with facts frequently exaggerated, that go to disprove their assertions. It has a very ugly enough proved that two can play at the game of exaggeration; and it is only a game, after all. It would be better to give it up, and be re-born to facts and business.

There is too much of this exaggeration business all around, and we are inclined, as we always have been, to the belief as expressed by the *Ledger* that the original source of the exaggeration lies within the electric camp. We do not take the *Ledger* lesson as intended for ourselves; for, although this journal for the past year has been an ardent advocate of the best and purest kind of gas for all possible purposes, its columns have not contained a single statement concerning any of the various electric systems that cannot be sustained and proven. We have made statements that have been repudiated by the electric-light folks and which have called forth several attempts termed "answers," but which for the most part have been merely volleys of vituperation. We have not indulged in billingsgate. Our staff, "from captain down to powder-boy," has been differently trained. We have simply held on our even way of truth-telling, and to-day as always we challenge any reader of this journal—and we have a goodly number of the electric-light folks on our subscription-list—to find in its columns a single word inimical to any system of lighting that the Western Department has opposed, that can be termed exaggeration. This invitation is open to our rival-gas friends as well as all others.

Perhaps the hardest words we have printed about any of the electric-lighting systems have concerned the Edison incandescent and its sprawling attempts to pull down gas-light stocks in New York. Our New York correspondent, who is a thoroughly gentleman and thoroughly posted in what he writes of, has given us some pretty hard facts concerning the Edison, and we have printed them just as he has sent them on. In this issue, in our correspondence columns, will be found one of the sequels to this gentleman's *expose* given in the November issue of the JOURNAL. We trust the inquiry made in this instance will be found sufficiently answered. If not, our columns will be open for any discussion that does not lead to scandalous advertising. We charge fair rates—and put them,—for our advertising columns. In this Edison matter we think the greatest mistake made by the incandescent folks was in opening their batteries upon a district lighted by water-gas.

In this connection we wish to state that this journal does not intend to and will not enter upon any crusade against the electric-lighting systems. This fact has been given out before in these columns, and we take this opportunity of re-stating our position upon this point. Elsewhere is given the platform of this journal and the interests it will represent. We can find nothing in any of the electric systems conflicting with the real interests of these interests, either in the present or future, and hence there is no reason for belittling the efforts they are making to give the world "more light." We are embarked in the same profession and with the same object in view, though our ways and means are different. We can but look on these electric systems as directly aiding the cause of gas illumination, and this view is borne out by a glance at the growing business of gas companies in all cities where the electric systems have been introduced. We believe there is a field for the electric light, and we shall not only not put a single stumbling-block in its path, but stand ready to aid in rolling away the stumbling-blocks that already lie therein.

Water gas and electricity have much in common, and the future will be found to bear out this assertion. While, however, we have naught but good-will too and for light that is older than gas-light, we shall take no hand in bolstering up its false pretenses and its exaggerated assertions. We shall give fair play all the time, but never foul play, for or against. We will not aid in the dissemination of the false statements put out in behalf of some of these systems, and above all things we will not rate a seven-candle lamp as the equal of a twenty-five candle gas-jet. A system that demands this much from its friends is not wanted within our circle. The gas-systems THE PROGRESSIVE AGE will advocate for the furnishing of light, heat and power, never to false or prevaricating statements to aid their introduction. They stand upon their merits and the merits alone. The electric systems that can so stand will have the co-operation of this journal,—if they wish it. Any system that cannot so stand had better keep on the other side of our fence.

pointing out that he misleads when he says the increase of mileage of 1884 over 1883 is only 140½ miles. He adds :—

"You have further included the Midland Railway as an additional line in March, ignoring the fact that the Midland existed and was self-dependent, as regards the interest on its securities, in 1883."

We should like some facts about the "self-dependence." We certainly do include the Midland as an additional line in a comparison of this year's figures with those of 1883 as stated last year. If not, how account for 280 additional miles of road, as shown in the following table?—

	1883 Miles Worked. Stated in 1883.	1884 Miles worked.
Grand Trunk and Great Western...say	1,255	1,262
Georgian Bay, &c.	1711	1714
Wellington, Grey, and Bruce.....	1611	168
Michigan Air	95	100
Montreal and Champlain	1611	624
Midland.....	.....	402
	3,222	3,902

This table shows 140½ miles plus 440 miles of the Midland.

We stated that the inclusion of the five subsidiary lines in this year's monthly revenue statements for two months had yielded £1,860 more than on the mileage as stated in 1883 :—

Net Earnings of Two Months Jan. and Feb., 1883 and 1884, Compared.

Miles.		
2,905 ...	Net Earnings in 1884 (Two Months)	£117,783
2,765 ...	— 1883 (Two Months).....	115,923
140	Miles more in 1884 than in 1883 Yields a Net Increase for 1884 of	£1,860

We may add that the adjusted statement of 1883 figures as given this year, compared with the statement as rendered in 1883, shows a net receipt of £8,600 in two months of 1883 on the 440 miles of Midland line then worked, or, say, about half the amount required to cover the bond interest of that Company. We tabulate the figures for reference, thus :—

Two Months' (Jan. and Feb., 1883) Net Earnings.

Miles.		
2,765 ...	Adjusted Statement, lately published ...	£117,518
2,325 ...	Statement as given in 1883	110,912
440	Miles of Midland Company Produced Net Earnings of	£8,606

On Tuesday, at the meeting, we had an answer to our demand for information respecting the interest charge on the subsidiary lines, though the facts were not so clearly stated as they might have been. Hamilton, Niles, St. Catharines and St. Lawrence, Buffalo and Lake Huron, and one or two small lines, requiring about £75,000 for interest, or, say, £37,500 for the half-year. The bond interest on five subsidiary lines we are now told is £78,200 for the current half, or about £13,000 a month. So we have an approximate visible half-year's charge of :—

Rentals—Atlantic and St. Lawrence, &c....	£75,000
Interest—Midland, Michigan Air, Georgian Bay, Montreal and Champlain, and Wellington ...	78,200
Total Rentals item for June, 1884....	£153,200

This £153,200 will compare with £83,814, the item for "rents" in the net revenue statement for the first half of 1883, which, however, did not contain the receipts of the Midland (40 miles and the 140½ miles referred to above.

A valuable item of information given by the President was that the Chicago and Grand Trunk, although in 1883 it paid off £10,274, is still indebted to the Grand Trunk £67,726 for interest paid by the latter during the period when the Chicago extension was not earning sufficient to cover its bond charges. Why, we would ask, has this fact been so long withheld from the proprietors? How has it happened that, with this debt accumulating half-year by half-year, credit has been taken in the Grand Trunk accounts for Chicago and Grand Trunk bond interest, as if it had been earned and received? We directed attention to the Chicago and Grand Trunk deficits on May 12th last year (*Statist*, page 522), and have asked again and again for particulars. Now we have them; and we see how ridiculous were the estimates made about eighteen months ago as to the imminent dividends on Chicago and Grand Trunk Ordinary Stock, even although the Chicago and Grand Trunk gross earnings in 1883 exceeded those of 1882 by just £118,000. Meanwhile, the Grand Trunk proprietors have been kept in the dark for eighteen months or two years, and have been beloaded with sanguine statements from quarters where either this debt of £78,000 must have been known of, —in which case the calculator who misled the public must be called by a hard name; or, if he did not know of it, he must accept the cap and bells. But we are dealing with the Company now, and we must say that particulars of a debt of such an amount is information which is manifestly withheld from their proprietors by Companies of respectable reputation." If any more similar debts are possible, the proprietors ought to insist on having the detailed information given them in the report.

Space will not admit of our considering the position of the 1,562 miles of roads none of which, we said, are worked on traffic guarantees. Last year the Grand Trunk Company hardly issued monthly statements of two of the Companies out of the six we named. More information might be given in future reports as to the North Shore and the Montreal and Sorel lines. The conditions between the Canada Atlantic, also the Central Vermont and the Grand Trunk Company too are little understood here. The Secretary says the Canada Pacific Company has not made arrangements with the Grand Trunk to acquire the North Shore road. By latest advices from Canada, we learn that it is expected another line is to be laid parallel to the North Shore, making three roads between Montreal and Quebec.

We have only endeavoured to do our duty in directing attention to the inadequate information afforded by the Company to the Shareholders—really a mild way of putting the case. One really might with justice express the opinion that the Company had resorted to *suppression vari*, even if its enabling interest-sheet debt was accumulating was not tantamount to *suggestio falsi*. Friends of the Grand Trunk Company have made much absurd calculations, and have caused so much misapprehension as to the real position, that we have endeavoured to warn the public against accepting misleading prophecies of only present things in the future. We have sought to tell the public the truth, so far as we have been able to dig it out of the well of meagre evidence, and we have warned them for months past of coming competition. It is now recognised that competition between Montreal and Chicago will be watered at once. We retain our opinion that the Grand Trunk policy of acquisition of subsidiary roads, which do not secure all their own bond interest, has failed in the main object of averting competition.

ELECTRIC LIGHT COMPANIES' PROSPECTS.

In returning to the subject of Electric Lighting, which we considered in our issue of April 12th—principally in connection with the Report and accounts of the Hammond Company—we now revert to the position of the Anglo-American Brush Electric Light Corporation, which, financially considered (as we have already shown) to be briefly summarised, as at December 31st last, as follows:—Against assets in hand in the shape of plant and buildings, stock, book-debts, and cash, amounting together to £129,549, the liabilities to creditors were only £7,898, and to Shareholders on capital account £118,277. This latter, we may here repeat, is on 7,791 shares of £5 fully paid (reduced from £10), and 26,992 shares of £3 with £2 paid (reduced from £8). With reference to this particular part of the subject, we confess we cannot follow the Chairman's line of argument in support of his proposal for the holders of the partly-paid shares to pay up their balances, as an advantage to themselves; although, of course, if the Company requires and can make good use of further capital (which is not represented as being the case), such a recommendation can be understood. This, however, is a point on which Shareholders must wait, if not to obtain the necessary information and decide for themselves. Neither do we by any means agree with the proposition, which has been informally mooted, to continue the system of extra remuneration to Directors when profits exceed a certain point. Any reason or excuse there may have been for such extra remuneration in the past, now, we imagine, no longer exists. The alleviation suggested with reference to this point would have the effect of giving the Directors a claim on profits when these are of only half the amount fixed under the old plan, 10 per cent. on the reduced capital representing an amount equal to 5 per cent. on the old. We suggest, however, that this is an undesirable method of remunerating Directors, which it would be better to abolish altogether.

As in the case of the Hammond Company, the process of "writing-off" in recognition of depreciation, &c., has been of a decidedly drastic nature—to the extent of £22,300 on patents, £8,300 on plant and buildings, and £17,200 on stock, making, with sundry liquidations of accounts, a total of upwards of £295,000 carried to the debit of profit

Engineering - Dec. 26, 1884

ELECTRIC LIGHTING NOTES.

ELECTRIC LIGHTING AT LAMBS.

A PERMANENT and very successful electric lighting installation has recently been carried out in the south of London, for the business premises of Messrs. Lamb, Limited, Incandescents, having been entirely fitted up with incandescence lamps. There are 32 lamps, each of 20 candle-power. Sixteen lamps are always running, and the remaining six are disposed in different parts of the premises. The dynamo used is an "A" Gramme, which is capable of giving current to thirty 20 candle-power lamps when running at the rate of 700 revolutions per minute. Power is obtained from a 7-horse engine of the horse-power nominal, and fitted with patent governor. Besides the six incandescence lamps already referred to, which principally form the auxiliary circuit, it also embraces a Jamin arc lamp of 1000 candle-power placed in the front shop on special occasions for lighting the street outside.

CONNECTING FOR PRIVATE ELECTRIC LIGHTING.

The question of allowing private electric lighting firms to run overhead wires or to open streets to lay conductors, was brought under the consideration of the Town Council of Glasgow at their last meeting. Messrs. Muir and Mossy, of that city, had sought the permission of the public authorities to do both of those things, for the purpose of successfully carrying out a contract which they have entered into for continuing the electric light at the General Post Office in Glasgow. Instead of having their motive power generated on the premises, as has been the case during the past three years or so in the contract originally taken by Messrs. Crompton and Co., they propose to have a power station in Miller-street, a very short distance away from the Post Office, and to lead their conductors either underground or overhead, or both. Their application was first considered by the Statute Labour Committee, and while engaged in their deliberations they adverted to a former minute which they passed when a somewhat similar application was made by Messrs. Mirrlees and Dawson, of Govan. The result of their deliberations was to recommend that Messrs. Muir and Mossy's application be not granted. Mr. Osborne Reynolds is to be informed of the great grounds on which the Committee had arrived at the decision recorded in their minutes. The contractors waited, he said, to take up the streets at once, where they would be at it all the way of every one; and he thought that every member of the council would be agreed that nothing could be more desirable than overhead wires. The question of power to lay wires under the streets was refused because they were to be used for the purposes of a general supply of electric light, whereas the application which they then had before them was one for a specific supply and besides that, the streets would only be opened for a very short distance. Under the circumstances he desired that the matter should be sent back to the Statute Labour committee for further consideration, as he could hardly believe that they had given it the consideration which it deserved, or they certainly would not have refused the authority asked. The convener of the committee replied that the reason which had induced them to refuse the application was simply that the applicants were private contractors, and that it was known that if it were granted other contractors would ask for similar permission. A discussion ensued in which several members took part. Some of them thought that the electric lighting enterprise should be encouraged by granting the permission asked. Another thought that the subject was not ripe for consideration, and he also urged that the corporation should by no means treat new required and erect a rent for the use of them. Two of the speakers urged that the matter should be reconsidered by the committee, and if they or the Police authorities were to ask the permission a reasonable exception might be made in their favour that would not be granted to private persons. It was eventually agreed that the matter should be taken back by the committee.

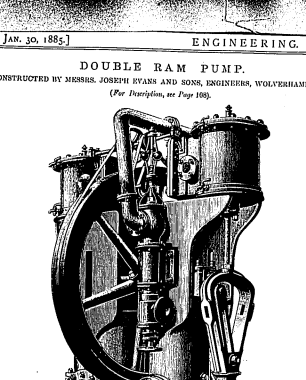
ELECTRIC LIGHTING IN AMERICA.

On Wednesday, the 10th inst., Mr. Preece read a paper at the Society of Arts giving the results of his observations on electric lighting in America. He said that there were probably 90,000 arc lamps in action every night in the States, and that there were many central stations doing a large business, and some even paying dividends to their shareholders. In nearly every case the wires were carried overhead, and the general outdoor installation showed a defiance of basis. The charge per lamp varied from 35*l.* to 60*l.* per annum, and the wires placed on high poles about 50 yards apart on alternate sides of the streets, no other lighting being used. The light was steady. Whilst using high voltage, as in Cleveland, where it was over 2500 it. high, the illumination was very poor. Incandescence lighting has not flourished to the same extent as arc lighting, and it has not been applied to private houses as freely as here. The principal system in practical use was that of Edison, but Mr. Weston was now introducing a new lamp. (This has already been described in our notices of the Philadelphia Exhibition.) The Edison central station, in New York, was opened on September 3, 1882, there havenearly been two and a half hours' stoppage since. There were now 587 subscribers, using altogether 12,761 lamps, served day and night. The price charged was the same as that which would be paid if gas were supplied at 7*s.* 8*d.* per 1000 cubic feet. The price of gas was 3*s.* 2*d.* per 1000 cubic feet. The system was worked at a profit, and during the past twelve months the balance on the right side had been sufficient to pay a dividend of 3 per cent. on the capital invested, but on dividend has yet been declared. The earnings per lamp-hour were 1.01 cents, while the cost of production for the same time was 0.71 cent. The charge made in New York was equivalent to 72*l.* per Board of Trade unit of 1000 volts. The average number of hours of lighting appeared to be 2.4 per day per lamp. A record was kept of every lamp, so that the average life was known, and it came out at about 477 hours. The consumption of coal was .82 lb. per lamp-hour, and there were five lamps per horse-power, rather a low result, due probably to the inefficiency of the old system of condensers. The average number of lamps per subscriber was twenty-one, while the average amount paid annually by each subscriber is 40*l.* The area lighted was about a quarter of a square mile, comprising fifty blocks of buildings and fifteen streets, and the capital invested was 200,000*l.* The system worked upon two more central stations, of much larger dimensions, in the upper part of the city. At Brooklyn, N.Y., there was an installation of 1200 lamps, supplied by three dynamos, in series, the lamps being also in three in series. Overhead wires were used, and the charge was 60*l.* per annum per lamp for each of the 1200 lamps, equivalent to 72*l.* on 2.5 mile, per 1000 cubic feet. At Brockton there was a station with 700 lamps in operation, and 1000 about to be started. The charge was one cent per hour per lamp, and there were 108 subscribers. Mr. Preece said he gave considerable attention to the question of safety, in which the current is measured by the electrolytic action of a fraction of it upon two silver electrodes immersed in a solution of plate of zinc. The method was scientifically accurate, and in practice gave results correct within one per cent. Two men spent their time in New York collecting these bottles, drying them, and weighing them to find the loss. There are 1160 bottles, fifty of which are measured every day. Mr. Swinburne, Mr. Preece is of opinion that the only feasibility of the electric light is amply demonstrated in America, but that it is unreasonable to expect that the great advantages can be obtained in this country at the price of gas. He believes that a greater cost and steady reduction will be made in the cost, and that in time people will find the advantages are worth the extra price.

DOUBLE RAM PUMP.

CONSTRUCTED BY MESSRS. JOSEPH EVANS AND SONS, ENGINEERS, WOLVERHAMPTON.

(*For Description, see Page* 108).



THE SOCIETY OF TELEGRAPH ENGINEERS.

ON Thursday, January 22, Mr. C. E. Spagnoletti, the new President of the Society of Telegraph Engineers and Electricians, delivered his inaugural address in the theatre of the Institution of Civil Engineers. The paper was a general review of the progress of the electrical industries of late years, more especially in the direction of telephony, railway signalling, electric lighting, and the transport of energy by electricity.

In telephony the recent establishment of the London to Brighton trunk line is a new departure which followed on the extended privileges granted to the telephone companies by the late Postmaster-General, the Honorable Mr. Fawcett. We understand that subscribers to the Brighton exchanges can use the new line without extra charge, thus making, as it were, a part and parcel of the metropolitan exchange system. The projected establishment of all-night telephone offices in the West-end, and the probable introduction of public call offices for talking by telephone at a fixed tariff according to the time the instruments are used, are other advances in telephonic development which are likely to ensue in this country.

The high rates at present charged by the telephone companies for the annual hire of the telephone, in exchanges and private wires, were adverted to by Mr. Spagnoletti, who expressed the opinion that these rates stood very largely in the way of the general employment of the telephone.

In telegraphy there was little that is new or late, except the extensive preparations that are being made by the Post Office to meet the requirements of the six-penny telegrams which are to come in August next. These preparations not only include the equipment of the new story added to the General Post Office at St. Martin's-le-Grand, but the erection and laying of new telegraph lines, both aerial and underground.

Railway signalling, a department with which Mr. Spagnoletti is himself intimately associated, has made steady progress of late, and as railway engineers and the directors of railway companies have their eyes opened to the advantages of electric signalling, they are showing greater readiness to adopt new arrangements.

The electric lighting of railway carriages is another still in its infancy, but destined to great importance in the future. There is no reason why a person travelling in a railway carriage should not be as comfortable in respect of heat and light and ventilation as if he were at home. The slight saving effected by providing a feeble glimmer which just enables a person to decipher the type of his newspaper by screwing himself into some uncomfortable attitude, is out of all proportion to the discomfort caused to travellers. Railway travelling ought to be a real pleasure instead of a kind of penalty which people undertake because they must. The delight of motion through new districts and in the fresh air of the country, the feeling of change and expectation, are elements in railway travelling which ought to make it positive and agreeable for its own sake. On the other hand, the uneasy seats, the draughts, and above all the bad light, very seriously neutralise these advantages. If the railway companies would only see that it is to their interests to entice people to travel by turning the journey into a pleasurable experience rather than a mere or less trying ordeal, the point would be grasped, and we should soon enjoy in every railway carriage not only a cushioned seat but efficient heating appliances, and what is still more needful, a bright and cheerful light enabling every passenger to read his book or newspaper in ease and comfort where he sits without the least undue taxation of the eyes.

Electric illumination promises to supply such a light; but Mr. Spagnoletti takes the view that it must be so arranged that however a train is disconnected and broken up or has fresh carriages added, none of the carriages should be in temporary darkness. Dynamos, primary batteries, and accumulators have all been tried for train lighting, but in Mr. Spagnoletti's opinion the problem has not yet been quite satisfactorily solved.

With regard to general electric illumination, Mr. Spagnoletti referred to the changes or as Mr. Ellison termed it, the "throttling" influences of the Electric Lighting Act. It seems tolerably clear that the terms of the Act were such that the money required to introduce the light on a large scale in one of the licensed districts, could have been raised from the public with difficulty; since it was quite problematical whether or not sufficient profits to compensate for the interest could have accrued to them. The recommendations of Lord Thurlow's Committee seem likely, we think, to remedy, if not altogether obviate, the defects which Mr. Chamberlain's Act manifested in the minds of undertakers without sacrificing its real efficacy in preventing the formation of exclusive monopolies.

The experiments of M. Marcel Deprez at Creuil on the transport of energy by electricity were also alluded to by Mr. Spagnoletti, who saw a useful future before Professor Fleeming Jenkin's telpherage system which is now at work on a small scale, and is capable of being used for conveying coals from mines, or slag from furnaces, and such like purposes.

With regard to the Society of Telegraph Engineers itself, Mr. Spagnoletti had only a good record to give. It is rapidly increasing in numbers and influence, and is now one of the youngest of the learned societies.

The Scientific library is being enlarged gradually by the donation, purchase, or exchange of books, and more space will soon be required to accommodate these. Mr. Frost, the librarian, has nearly completed the classified catalogue of which the intention on which he is engaged, a catalogue which will greatly aid to the economy of time in literary labour. It will enable a student to refer to works on special subjects, although he does not know the names of their authors. It is, we think, a serious imperfection in the British Museum catalogue that, in order to find a book on a particular subject, one must know the name of the author, for purposes of research it is the subject which is of most importance to the student, who is frequently ignorant alike of the names of the books treating of it and the names of their authors. The plan in high literature it is oftener the title of the work than the author's name that a reader is likely to know.

Mr. Spagnoletti expressed the hope that the Society would before long possess a lecture-room as well as a library.

Such an institution would no doubt be useful to some members of the Society, especially students. A place to which a student or an inventor can go and make a few experiments to test an idea or verify a fact, would seem in theory to be a real boon, and the satisfaction of a want which has sometimes been felt. We must remember, however, that such a laboratory would have to be at once a free and a private place. To insure its useful character there would have to be very few restrictions or official red-tapism imposed upon its use by

ELECTRIC LIGHTING NOTES.

The Electric Lighting Act.

Soon there came the "Dynamiters," the association of electricians and others interested in electric lighting, appointed a very influential Committee, under the presidency of Lord Hury, to consider the Electric Lighting Act of 1882, and its influence upon the progress of the new industry it was professedly designed to foster, and this Committee have published their report. They have received: 1. That the Act of 1882 may be made workable by the omission or alteration of two or three clauses. 2. That the forced provisional order adopted by the Board of Trade is wisely severe, and requires no amendment in two principal and a few minor points. 3. That the form of provisional order adopted by the Board of Trade proceeds on erroneous interpretation of the third clause of the Act, and should be remodelled. The principal clause to be modified or altered is the 27th, which provides that the whole cost of the undertakers may be compulsorily purchased by the local authority at the end of twenty-one years, or at the end of each seventh year afterwards, at the net value, free of all compensation or goodwill. This means that the undertakers are subjected in for a fraction of what it cost them, and if they are to avoid loss they must commit themselves to an exorbitant sinking fund annual equal to their original capital. If district electric lighting were an established industry of which all the details were understood, there would be still somewhat serious conditions, because a very considerable portion of the term of years must elapse before the enterprise gets into full working, and during that time the provision could be made for its dissolution. But as matters now stand they are simply prohibitory. No sane person would invest money in an unknown industry if he knew that inquiry many and costly experiments to perfect it, and which will be fought tooth and nail by powerful opponents in Parliament, with the certainty that all the profits will go to the municipality, and all the losses to himself. It is simply a case of "heads I win, tails you lose." The Committee therefore expressed the opinion that if the term of twenty-one years should be extended, and they recommend that it be extended in perpetuity, or, in short, be repealed altogether. They also object to Clause 24 by which the undertakers are deprived of all power of controlling the use to which electricity is to be put by consumers. At present if there is no nuisance to be abated, and therefore the only basis of payment is an agreement of as much per horse-power, the kind of lamp being necessarily specified by the undertakers, a system which is distinctly contrary to the interests of the public. The Committee also recommend that when the local authorities are themselves holders of provisional orders, they should not have an absolute veto on applications for licenses in their district. As to the form of provisional order which has been adopted by the Board of Trade, they recommend that it shall be amended by two fundamental points: (1) the provisions as to the compulsory laying down of mains should be altered, and the undertakers should be allowed to determine for themselves what sections are to be laid down; (2) the power to register a supply should be limited to customers who are prepared to take the supply continuously for during 1000 hours in the year at least. The Committee further are of opinion that all inspection of the undertakers' wires and works should be in the hands of the Board of Trade and not of the local authorities. They hold that the Board of Trade has proceeded on an erroneous interpretation of Section 3 of the Act in regard to the limits of area, and they recommend that this should be amended so that the holders of licenses should be permitted, with the consent of the local authority, to use stations for the generation of electricity for supply on any way undertake to give without being required to give any other or public supplies. In undertaking the Committee has not offered a definite working proposition in place of his existing (27th section. All are agreed that it must be modified, and the only question at issue is to what extent should the alteration go. But it is not of the question that it should be simply repealed. There are some who hold likewise the public have a claim has been imperative, matter of electricity that it would not accept any scheme. But of this we have very grave doubts. At present, it is about the maximum interest that can be secured for investments, and the risks are considerable in some respects which will, we should produce a considerable energy competition and pressure, and many available spot in the kingdom would be pounced upon. It would matter little whether there were one hundred undertakers or not, if a steady 10 per cent. dividend in the first few years, with the license in the hands of the local authority, and the control of the provisional order it would be easy to keep the installation in the district. Until some new discovery in electricity intervened to put the whole thing on a perfectly different footing, or the monopoly of the electric light there is no doubt, and would be deferred for many years, and in the meantime those who can well afford to secure their capital by doing the monopoly of the supply at the expense of a present loss. The clause I mention upon which the struggle turns, and until that is settled it is useless to discuss details of provisional orders. We await with confidence the report of Lord Thurlow's Committee on this point, for we expect it will contain a graver sense of responsibility than that possessed by Lord Bury, and Mr. Chamberlain has promised to give their proposals his earnest consideration.

The Electric Light in Industrial Establishments.

It is now universally conceded that the value of electric illumination in industrial establishments is measured by its intrinsic worth in several particulars, each tending to increase or improve the production summed up in the one general phrase rather than its cost in comparison with other methods of lighting. An unexpected merit in electric illumination was recently forced upon the attention of the agent of a large mill corporation in the United States, engaged in manufacturing fine sheetings, who introduced an incandescent electric lighting plant, which lighted about half of the mills, the remainder being lighted as before by gas produced from the destructive distillation of petroleum. He received a letter a short time later from the bleachery where the goods were finished stating that the force of workmen reuse about one-half of their goods appeared dead and lustreless in comparison with the extra finish obtained upon the remainder of the goods, which had been subjected to the same processes. The result of a very careful investigation showed that the unsatisfactory appearance of the cloth was due to the small motes of carbon deposited by the burning gas, and that the freedom from such unsuccessful matter in the mill where the electric light was used rendered possible the more brilliant finish to the goods.

The German Edison Company at Berlin.

Electric illumination is making considerable progress in Germany, and some of the installations recently executed probably count among the largest in Europe. Berlin is about to have a central station for the supply of current for both arc and incandescent lamps, the former Siemens, the latter Edison; and the plant now being erected will be capable of supplying 1800 incandescence lamps, distributed in shops, restaurants, and private houses.

A central installation recently inaugurated is that at Münich, supplying the two chief theatres of the town, the Hof and National Theatre and the Nindtne Theatre, with a total of 2500 incandescent lamps. Steam is generated by three boilers of every 1000 square feet of heating surface each, fired by Bavarian coal, which hitherto could not be used for lighting purposes, being a very poor gas-producing coal. Three high-speed compound engines with a total of about 350 horse-power drive the Edison dynamos of 450 lights each and one smaller size for 250 lights, all of 16 German standard candles each, which is equal to 20 English standard candles. The small machine is chiefly used for night time. The engine-house being nearly 300 yards distant from the theatres, eight underground copper cables of nearly half a square inch area each, well insulated, and laid buried 3 ft. deep below the surface carry the current across and supply a network of nearly 22 miles of leads. The lamps are used all over both houses, on the stages, the auditoriums, and all other offices, rooms, &c. Several are hanging for the purpose of special stage effects are also provided. The Münich Edison installation on the opening day of the two theatres, the 19th of January, gave every satisfaction. We hope in a future number to be able to place before our readers more detailed information relating to this at present largest electric light installation in Germany.

---

would dread lost under some contingency it would fetter his action.

Thus in two extreme cases, very far apart, it would seem that the scheme of co-operation before us, in spite of its great theoretical advantages would not work, and if we were to make intermediate examples it would be evident that they bristled with formidable difficulties. The conviction is forced upon us that in social, as in physical questions, a mean in one part of the organised structure cannot take place with an alteration in other parts, and must be very gradual. Changes in our business environments are doubtless taking place, but the present question must have grown much more unsatisfactory than it is, before capital and labour, the most fluid and the most indiscriminating elements of our system, will voluntarily adopt a change, the effects of which cannot be clearly foreseen. Doubtless something of the kind will come, and cautious experiments are to be recommended. The plan of giving managers a consciousness of the profits has worked well for a long time, and affords a machine for extension in time to come, and even to leading hands. Such a trial, if successful, would furnish a base for which a plan such as Mr. Waring's might grow. It is when trouble is very bad indeed, and for the same reason we do not expect to see any earnest attempt at co-operation until the workman feels that his real interests depends upon it, and the capitalist find it to be the only means by which he can employ his money.

ELECTRICAL PROGRESS IN AMERICA.

At the meeting of the Society of Telegraph Engineers and Electricians on Nov. 26, Prof. D. E. Hughes, F.R.S., gave a most interesting discourse on the present condition and future prospects of electrical engineering in America. The author visited America in 1877. In order to meet the heavy tireless of the system, on behalf of the Postal Telegraph Department; and his second visit was made during the recent meeting of the British Association at Montreal and the holding of the Electrical Congress at the Philadelphia Exhibition.

After explaining the work done at both of these scientific gatherings, Mr. Preece went on to speak of the enormous progress which had been developed in the United States, remarking that since 1877 there had been an increase in the number of telephones from 30,000 in 1877 to 433,726 in 1884, while the number of messages per annum has increased from 28 millions, to 48 millions, in the same space of time. The number of offices has risen from 11,000 to 19,000, and the capital invested from 40 millions to 80 millions of dollars. One telegraph novelty had indeed appeared, namely, the system of Professor Hughes. Prof. Preece speaks very favourably of this rapid telegraph, and we hope to try it on the Postal Telegraph lines. The apparatus itself will, we understand, be exhibited at the forthcoming International Inventions Exhibition in South Kensington.

Passing from telegraphs to telephonic operations, Mr. Preece alluded to the recent attempt to set aside Edison's patents on the ground of Dolbear's claim to priority of invention; a claim which has been for ten years before the courts, pending an appeal to the Supreme Court, and Judge Wallace has decided that notwithstanding the testimony of some 200 witnesses who could be called on board, or here after the Dolbear telephones prior to the date of Bell's patents, the evidence was not sufficient to show that Dolbear had not invented a practical telephone prior to that date. The case has been pending for four years, and the interests involved are at present valued at 10 millions sterling. That is a question will, if unnursed, give an impetus to telephony in America by preventing threatened litigation. From 150, the stock of the Bell Company has risen to 270 in less than six months, owing to the termination of the case in the Circuit Court.

The telephone in America (to return to Mr. Preece's lecture) is used on a far more extensive scale than in this country, notwithstanding the fact that it is far more heavily taxed than here, one company being taxed as much as 75 per cent. of its receipts. The reason of this is that it is practically necessary to business, partly owing to the excessive heat during summer. The charges for the use of the telephone are also much higher in America than here, the annual charge for the "law" exchange system employed by lawyers being 120 dols., while the ordinary charge is 250l., as against 20l. in London. In some American towns a service—for example, Philadelphia—the rate is 25l., and in Buffalo they charge by meter as high as 2 cents, or 1d., per message, according as the minimum number of calls is 600, 1000, and over 1000 per annum.

The exchange system is very promptly worked in America, the maximum time of "putting through" being four seconds, as in Brussels and Berlin. There are 10,000 subscribers to the exchanges of New York alone, whereas in all England there are only 11,000. In the whole United States there are 97,400 circuits, comprising 90,000 miles of wire, and some 517,000 instruments have been manufactured.

Turning to electric lighting, Mr. Preece remarked upon the extraordinary progress it has made in the United States as compared with Great Britain. There are some 80,000 arc lamps alight every night in the States, and in most of the large cities they are in constant use, and are brilliantly lighted by them. The contrast between New York and London in this respect was, as Mr. Preece stated in a recent lecture to the Society of Arts, most depressing. "On the night of October 21st," he said, "I drove from the Windsor Hotel, down 5th avenue, the Cunard Wharf, a distance of about four miles, through streets entirely lighted by electricity. On October 30th I drove from Euston to Waterloo without seeing a single electric light." One manufacturer told him that he was turning out 800,000 carbons for arc lamps per month, and another that the output was 50 arc lamps and 3 dynamos per diem. These are only samples of the items now working regularly, both with arc and incandescent lamps, and where these are established they pay dividends; while the manufacturers seem to be all busy.

The principal systems in use are, for arc, the Brush, Weston, and Thomson-Houston, and there are other systems not so well known on this side of the Atlantic, such as the Hochhausen, the Van de Poel, the Western Electric, the Fuller, and the Sperry. The chief incandescent system employed are the Edison and the Weston.

In his lecture to the Society of Arts, Mr. Preece entered rather more fully into this part of the subject. He first described incandescent lamps as employed in the United States, remarking that since 1877 there had been advances made, notably that the carbons, a remark which is contrary to the received opinion. It is a fact, however, in a scientific rather than a material sense, as Mr. Preece pointed out, and he showed a slide to illustrate it. The Edison dynamos of 1882 were 125 horse-power each, while those now in use are of 350 horse-power each. The Edison lamps of 1882 were 16 candle-power each, while those now in use are of 20 candle-power each

ELECTRIC LIGHT AT THE CE STATION AT BUDA-PESTH.

An electric light installation of some has been in regular work for some time s so far proved very successful; it is i tion of the new Central Railway Station at to which we have already previously refe columns." It has been carried out by M and Co., of Buda-Pest, and contains arrang of 600 standard candle-power each and distance lamps, of which 250 are of 20 c and 435 of 12 candle-power each. The arr distributed as follows:—Two outside fi over the entrance, two on the arrival pl four in the sliding roofs. The departure which has a roof nearly 100 ft. high, is ligh gether fourteen arc lamps, of which four roof and five on each side platform. T ment way has independent illumination, o twelve arc lamps mounted upon wrought posts 27 ft. high; two more lamps are lighting the line on the starting side of t; with ten are placed in the ticket offices an in the refreshment rooms. The postal off four lamps, the luggage office five, the waiting-room three, and the covered yard postal service contains the remaining 2 These are lamps, which are all of the 2 system, are partly constructed for a single base, capable of giving light for eight hours; have double carbons with automatic switc burn for sixteen hours. The wires are i arranged in such a manner inside the lamp they are not visible from the outside. T lamps are divided into seven series of ten a each lamp working with a current inte amperes and 42 volts. The main wires are and each 9,16 in. in diameter; any lamp can of the main circuit, the length of which 750 to 1200 yards, while their aggregate nearly 12,000 yards.

In the distribution of the incandescent space to be lighted was carefully consid lamp of 12 candle-power provided for every feet. No very large number of the cry are used, as they are liable to cut out of s system. The main cable consists of a pair, and 0.87 in. in diameter, insulated by ca masked in shellac; this is placed in iron pi boxes, spaced by wood bearings, and the sp up by molten asphalte. Each single lamp such series, is fitted with a fusible cut-out the leads are made of such dimensions that a fault of additional lamps to the extent of 1 Figs. 1, 2, and 3 of our illustrations on page arrangement of the boiler and engine of th tion. The building is 88 ft. long, 45 ft. 10 ft. high, and is divided by a central wall equal parts; one containing the three boilers

THE YORK DEMOCRATIC

THE EDISON LIGHT.

ITS WONDERFUL ILLUMINATING POWERS.

And Adaptability to the Use of Stores, Banks, Hotels, and Private Families—Another Grand Exhibition of the Light on Saturday Night.

The exhibition of the wonderful Edison and only incandescent system of electric lighting, on Saturday night last, eclipsed all the former displays of the light made in York. Hoffman's Clothing store and the Morris Drug store were in a blaze of soft, beautiful white light, which illuminated the sidewalk and street to the opposite curb. From the top of the hill on East Market street, looking in the direction of them two stores the difference of the Edison light over that of gas was so marked as to almost leave the impression that the two stores using the electric light were on fire. The same night presented itself from any of the elevated points of view in one looking in the direction of these stores. At THE ERA office, where the dynamo is located, there was a flood of light, to which you could look into for all its transcendent intensity and not tire the eye or affect it in the least, and this is the only light which does not dazzle the eye and blind the sight. The wonders of the dynamo were witnessed by hundreds of people, all of whom were in ecstacies over the simplicity of the arrangement, and the grand results obtained from it. The light speaks for itself, and so magnificently that our people are overwhelmed by its perfection.

We have had exhibitions here of Arc lighting, with its flickering, dazzling and painful effect upon the eyes, and the difference of the Edison incandescent is so marked and so different, that all unprejudiced people vote the Edison the nearest approach of artificial light that of sunlight yet invented.

THE SAFETY OF THE EDISON LIGHT.

There is no danger to life, health, or person, in the current generated by any of the Edison dynamos. The electric current is so feeble that the wires at any part of the system, and even the poles of the generator itself, may be grasped by the naked hand without the least effect; in fact, the current is imperceptible to the touch.

WE MUST HAVE THE LIGHT.

York can now the opportunity to secure this grand illuminant, and it is to be hoped that the opportunity will be taken advantage of. The canvas made among our merchants has met with success. Quite a large number have subscribed for the light. But it should on account of its safety, cleanliness, freedom from odor and great brilliancy find its way into every store, church and dwelling in York. Our street lamps should also contain this light, as it would make our thoroughfares as bright as day and safer than they are under the very inferior gas lamps. The much needed reform in street lighting, however, has a little sleepy position to overcome on the part of some of the gas people in the old Council. When it came to the renewal of the gas contract for the city, the borough was trapped into a three year contract. We question the right of this procedure and hope the Chief Burgers will use his influence to annul it. We have no right to be bound to a monopoly, and compelled to use their inferior light, no matter how bad or inefficient, just because, fearing the electric light would come into York, they would block its way by introducing themselves with a contract for the city lighting with gas for three years. Annul the contract and give us a good light.

SOME OF THE ADVANTAGES OF THE EDISON LIGHT.

Add to this pecuniary economy the healthfulness of the light as compared with that of gas, its freedom from odor and from danger by fire, its steadiness, adaptability, completeness, and beauty, and there can be no doubt that the Edison light is unsurpassed by any other method of artificial lighting whatever.

The advantages of this light are so great that it would occupy our entire paper to enumerate them, we will therefore speak of only a few.

In the cities where this light is now in general use, all the merchants and banking houses have a button placed at some point on the door or window framing known to the policemen on the beat. If the policeman on passing the store or bank hears a noise within or is suspicious of a burglar operating there, he touches the button and turns on every light in the store, allowing him to see all through the place at a glance. In private residences a button is often placed on the head board of a bedstead. Should you need a diurnal light in case of sickness, or by the entrance of a burglar, press the button and you have a light as by magic; and all this you can have just as cheap as gas, and much cheaper when you consider the superiority of the light furnished. Then there is an almost entire absence of heat in the Edison light, which will be a very desirable thing in its favor during the hot nights of summer, especially in the churches and public places.

THE ARC is progressive. Quite a few days ago it was the same as tallow dips, and it is time to shoot the gas and turn on the electric. Other towns and cities around and about York have long since adopted the electric light system, and can't let us lag behind any longer, but light up the town with a decent illuminant.

The gentlemen who are interested in the Edison light are our own citizens. They furnish you the light anyway you want it. Will contract with you for a certain number of lamps by the hour and you in a meter and register as amount you consume. Let us show our storekeepers and everybody in line, and even in the suburbs to use the grand illuminant.

STEAM HEATING.

The company introducing the light will also be able next winter to furnish steam heat for public and private buildings, which is another progressive step, and one that will meet with success. We don't know much about the company's plan of operation, but we learned from what little we have learned, that stock can be purchased and anybody allowed to come in and share in the investment who desires to do so.

INCANDESCENT REFRACTORY SUBSTANCES FOR ILLUMINATING.

A PATENT has been recently taken out in this country, by Otto Pulvermüller (5416, 1883) which has for its subject a method of obtaining or producing light of superior quality by convenient and economical means. We are unable to ascertain whether the patentee has made any practical experiments; but the method seems to be of a promising nature, and we therefore give an account of it for what it may be worth. The invention relates also to the manufacture of suitable refractory substances in the form of small wire, plate, or bands, these being fixed in suitable holders that they may be capable of the necessary adjustment; and secondly to a method of causing the incandescence of these refractory substances by the action of the heat caused by the combustion of the mixture of gases, commonly known as "coal gas" in air, at the ordinary temperature and under the ordinary conditions of the atmosphere.

The substances out of which the small wire or plate are constructed are refractory oxides, such as those of magnesium, calcium, strontium, or silicon, either singly or mixed together in suitable proportions; magnesia has been found to be generally preferable. (Cf. Clamond incandescent light, p. 144, Vol. XXXVI.)

A convenient method of manufacturing the small wires, plates, or bands is by wet mixing the finely-powdered oxide with a solution of starch, gum, or other gelatinous substance, in such proportions as to obtain a plastic mass. By pressing this through a small die, a thread may be obtained of a desired thickness. This thread, while still soft, may be cut into pieces of the required length, and these may be made straight or bent into any desired form. They should then be dried, and afterwards burnt at a high temperature. If the burning be omitted, the wires are liable to twist and bend when exposed to the heat of the "coal gas" flame. A number of these small wires are fixed in rows or rings in a socket, so as to be capable of certain adjustment in order to obtain the full effect of the heat. Both supporting and holding is proved in "combs" the model is contrived of two, which, in other words, are two rows of wires, set into a frame. This is filled with a plastic mass, such as damp clay or magnesia, and the wires are fixed in such a manner as to be capable by inserting one and in the soft mass which is afterwards well dried. The combs may be straight, curved, or circular, according to the kind of burner for which they are intended, and to subject the wires, and they should be provided with some device for the adjustment necessary for fixing them to a support, by which they are suspended in the burner. This support should be capable of being moved at will in every direction, in order that the necessary adjustment of the comb may be thereby obtained. If the wires, pins, or bands are to be used in the form of loops, a comb may be formed by arranging the wires so as to cross each other. The wires may also be mounted on the supports that they may be easily replaced, because as the high temperature of the "coal gas" flame all the refractory substance of which they are composed are more or less volatile.

The modes of producing "water gas" are well known, and have been made the subject of several patents. A convenient method of production is by passing steam over coal or coke at a high temperature, the mixture of gases thereby produced consisting principally of hydrogen and carbonic oxide.

This "water gas" may be conveniently burnt in gas-burners of the form generally used for the combustion of ordinary illuminating coal gas; a modification of burner which has been found preferable is that known as a fish-tail burner.

The Engineer — Sept. 2, 1881

DOMESTIC ELECTRIC LIGHTING.

By Mr. W. H. PREECE, F.R.S.

The author commenced by expressing his surprise that he had been only one example of domestic electric lighting in Canada. In 1879, however, had been the first in England to do this, and before leaving the Continent had followed suit, himself being one of three. Of course, in the first case, there were not what troubles and difficulty would be avoided if a number were estimates to be had in plenty, which were themselves a source of losses, three did not represent the whole aspect of the question. He had built in his garden an engine house, and had placed in it a 3-horse power gas engine and dynamo, the current from the latter being 30 lamps, with an electro-motive force of 42 volts, and consuming 2 horse power. The horse power as the result, which showed a very high efficiency. There was a gas into secondary batteries, and the gardener, when he comes on duty, first charges the gas engine and charges the cells, but Mr. Preece now proposes to have a sufficiently large battery to enable the charging to be done only once a week. The author then proceeded to give an account of various special features in the lighting of his house, and the experience gained. The cost of the whole was £700, the actual cost per lamp was £7 10s., and he could not understand the actual cost was greater, when working twice as much as he was only employed from one-half to one-third of the time, and caused no trouble, it was greatly to be preferred. He spoke of the great tolerance to the progress of electric lighting by the most unfortunate Act of legislation which had been enacted for some time, but in spite of the Act the progress was steadily going ahead, and mentioned some of the places in which this was actually the case.

Under W. Preece, in the discussion on this and the previous papers of Mr. Preece, said it would be vastly more convenient to have a unit of work regardless of a name power, and, about 1866 Watts, instead of dividing constantly by 746, which involved a troublesome sum in division, had proposed to work strongly for the adoption of the electric unit. Speaking of lighting, spoke of the application for the purpose of the water power at Niagara Falls. Canada, and considered it of the highest importance, which was so close to the town of Montreal. He also emphatically endorsed what Mr. Preece had said with reference to the dangerous effect of present legislation with regard to electric lighting. Professor Crompton, the well-known engineer, both spoke of the cost of electricity, the latter saying that a friend had supplied his mews with energy immediately behind his house, and the cost of the whole assembly has cost him 7s. 6d. per week. Professor Crompton mentioned that Mr. Preece had originally wanted to employ a 50-horse power engine for per hour, and produced a light of 32-candle power, whereas if he had used a 10-horse power he found he could produce light, only 24-candle power would have resulted.

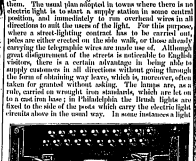
Iron — Aug. 8, 1881

THE WERDERMANN LIGHT FOR THEATRES.—A most successful experiment with Werdermann's illuminant was tried on March 30, at the Athenæum of the Rue des Mathurins, Paris, with the kind permission of Mr. Perrin, the director. The peculiarity of it is that it can be produced at will for scenic effects, either by introducing resistance and so varying the velocity of the Gramme machine. These experiments were witnessed by several influential members of the Municipal Council, who on the following morning proposed an inquiry into the pecuniary advantages of the illuminant compared to light their halls with electricity.

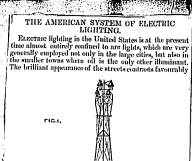
THE ELECTRIC LIGHT AT THE CANNON STREET STATION.—The Electric Lighting Street lights were not the only systems which lighted up on Monday last. Work for the first time. The electric light was also used on the first time on the same evening at the Cannon Street Station. The premises are supplied with 4 Gramme machines and 2 Brockie arc lamps, and the work has been carried out by the British Electric Light Company who own these patents. Eight powerful lights of 6000 candles each are suspended from the roof of the station at a height of about forty feet from the platforms, and there are two lights outside the station. There are two circuits for the two lights, five upon each, and the current for each circuit is produced by one of the large size Gramme machines recently introduced by the British Electric Light Company, which work a number of lights in series. The same class of machines is used by them for lighting Lincoln Station, Manchester, and numerous other places, and for the purpose of lighting the telegraph instrument galleries and letter sorting rooms of the General Post Office. Although as small a number of lights are employed at Cannon Street the station is filled by a brilliant and well-diffused light. Although the British Electric Light Company have taken no part in the City lighting they have entered into a contract with the Liverpool Companies for lighting about 25 miles of the principal streets of that city, and it is expected that the lighting of this large area, with city lamps will commence on the 1st May.

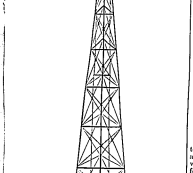
light; still it was found that each of them cost the city just about double what was being paid for electric light. Those torches, as they are called, were set up to show that gas is improved burners could compete successfully with electricity for extensive illumination; but the result has been most disastrous to those concerned in the undertaking. The average price of gas in the United States may be taken at 2·4dls. per 1000 cubic feet; in some places, however, it is customary to allow a rebate for each of 20c. to 30c. per 1000ft. The usual contract price for electric light is 80c.—5s. 7½d.—from dusk to midnight, or 7hr. from dusk to daylight; and this price includes carbons and maintenance of the lamps in good repair. The Street Commissioners of the city of Hartford report: "Where the gas lamps burning twenty-six nights per month cost the city 25·30dls. each per annum, experience shows that each electric light displaces 62 gas lamps, and gives at least ten times the light. At 62c. per night each, these electric lamps burning twenty-eight nights per month instead of twenty six, cost the city 211·20 dls. per annum each, against 227·50 dls. for the 25 gas lamps, showing a net saving of 15·80 dls. per annum for each electric light."

The companies principally engaged in this business are those employing either the Thomson-Houston, Brush, or Maxim-Weston systems; the first, although the latest in the field, is rapidly distancing its competitors both as regards the number of lights maintained and the cost of them. The usual plan adopted in towns where there is no electric light is to erect a supply station in some central position, and immediately to run overhead wires in all directions to suit the users of the light. For this purpose, where a street-lighting contract has to be carried out, poles are either erected on the side walk, or those already carrying the telegraphic wires are made use of. Although a good disfigurement of the streets is noticeable to English visitors, there is a certain advantage in being able to supply customers in all directions without going through the form of obtaining way leave, which is, moreover, often taken for granted without asking. The lamps are, as a rule, carried on wrought iron standards, which are let on to a cast iron base; in Philadelphia the Brush lights are fixed to the side of the posts which carry the electric light circuits above in the usual way. In some instances a light



tower is erected, which is either of an open work design, as shown in Fig. 1, or consists of a central pole, round which the arc lamps swing in a frame, which is lowered for trimming purposes. The tower system does not appear to increase in favour, but has its advantages for open sites, and has been adopted by the authorities for lighting the land of the East River, New York, where the obstructions known as Hell Gate has been removed. The tower in question is of the description illustrated, and is 175ft. high. The question of lighting from central stations has often been discussed, and certain difficulties have been brought forward, such as the noise, and the consequent nuisance in adjoining property. These objections have been met by special arrangement of the machinery, and stations are now found in the most busy streets of the American cities. One of the newest is that erected by Moreland's Light and Power Company, of Boston, which consists of a basement and dynamo-room above, the length of which is 110ft., basement, ventilation being maintained by two fan blowers. Coal is run into bins from the street; it is then mixed, weighed, and transferred to the furnaces by small cars. The engines, which are all of the Armington and Sims pattern, are in the dynamo room, and are in the centre of the room, the Thomson-Houston dynamos being in a long line on each side. The wiring is arranged so that the negative wires from the dynamos run under the floor, as are also the short-circuiting field wires, while the positive wires are run along either wall, and on the ceiling are those leading to the arc lamps, one of each is included in each working circuit. The switch board is of special design, the plugs being used which are so arranged that the circuit can be easily changed, and by means of wire leading from the field magnets to the board, they can be short-circuited so that the current may be interrupted without causing any flash. In smaller installations the distribution switch shown in Fig. 2 is employed, which fulfils the same purpose. When finished, this station will contain sixteen engines and thirty dynamos, each producing thirty lights. There are forty smaller supply stations now at work under license, and as prices of a single system, and only represent the motive power. Very lustrous arc lighting throughout the United States and contrast it with the results obtained during the same period in England. With reference to Fig. 2, it should be noted that the loose handles on each side are slid on the brass pieces





with those in England, as with a very few exceptions are lighting for streets is a thing of the past, and we are relegated to what, under the very best conditions, is a poor substitute, namely, gas. In America, as at home, the gas interest is controlled by powerful companies, and it is to be supposed that these have given up the battle and allowed their electric rivals to obtain the contracts for lighting the streets without great opposition. In New York and Boston large lamps were erected burning each from six to sixteen lights at such gas as the ordinary street burner; the price of gas was cut down to about one-

* This number varies according to the arrangement of wire gear adopted.

ELECTRIC LIGHTING IN THE CITY.

OUR readers are doubtless aware that a portion of the City is to be illuminated experimentally by the aid of electricity. Three districts, in fact, are to be electrically lighted, the first by Brush, a second by the Siemens, and a third by the Lontin light. The Jablochkoff light was to have illuminated one district, but circumstances have arisen which prevent this arrangement being carried out, and the district has been allotted to the Lontin light. The district which has been undertaken by the Anglo-American Brush Electric Light Corporation embraces Blackfriars Bridge, New Bridge Street, Ludgate Circus, Ludgate Hill, Saint Paul's Churchyard (north side), and Cheapside, as far as King Street, and is the second largest of the three districts experimented upon by the City authorities. The lights are thirty-two in number, although forty lights could be maintained on the same circuits. The whole of this section is worked by a single small copper wire strand of 8 B.W.G., and 20,000 feet, or over 3¾ miles, in length, starting from the works of the Anglo-American Company, near Waterloo Station. The whole number of lights are connected in one circuit and worked by one machine, absorbing for the entire circuit about 28 horse-power indicated. The machine is worked by the same engine which works the lights running at Charing Cross and Waterloo Stations, as also all the machinery and the testing circuits of the Company's factory. The lamps are fixed upon the present gas-lamp standards, above which they are raised about 4 feet 5 inches. The street lighting, in fact, is being carried out by the Brush Company, so as to show the utilisation of existing gas standposts with the view of demonstrating how economically a large town gas in the electrical supply and lighting streets can be effected. If it is considered that the present effect would be increased with the higher standards, they can, of course, be easily fixed; but in the experimental trial, both as to gas and lamp-posts, the greatest economy has been aimed at. Keeping this point in view, all the lamps in the district lighted by the Brush Company are of a power which is estimated to be that adopted for such a purposes, but light of any greater degree of power can be substituted if desired.

The district allotted to Messrs. Siemens Brothers and Co. extends from the south side of London Bridge, through King William Street, the Poultry, up to the Guildhall Yard, taking in Queen Street as far as Queen Victoria Street. The number of lights employed is thirty-four, comprising six powerful lights, and twenty-eight smaller ones of about 200 candle power each. The six large lights are mounted on latticed iron poles 80 feet high, two above the level of the street, and are disposed, one in Adelaide Place, a second at the New William Station, a third at the junction of Lombard Street and King William Street, the fourth in front of the Royal Exchange, the fifth by the Mansion House, in Queen Victoria Street, and the sixth in the Guildhall Yard. This last light is nearly three-quarters of a mile from the dynamo-electric machine which creates the current for it. The twenty-eight smaller lights are fixed on iron posts resembling ordinary gas lamp-posts, more so feet from the ground, and interspersed between the larger lights in the best manner to secure a good general illumination. Each large light is supplied by its own dynamo-electric machine, separate conductors being led from the dynamo machines to each large. The twenty-eight smaller lights are arranged in four groups of seven lights each, and are fed from two alternate current machines, each supplying two groups, or fourteen lights. It has been thought advisable to make this subdivision for convenience in working, instead of arranging all the lights in a single group, as could easily have been done.

The regulators, or lamps, are constructed to take carbons of sufficient length to last eighteen hours without renewal. They are enclosed in lanterns fitted with reflectors designed to be internal and throw down the upward and horizontal rays. The lanterns are suspended from the tops of the latticed iron poles by projecting brackets, against which they are drawn tightly to prevent their being blown about by the wind. About 16 feet above the street a platform is fixed to the pole, upon which the lantern is lowered when it becomes necessary to replenish the carbons, guide wires, passing through openings in the collector, being stretched between the platform and the bracket to guide the lantern during its ascent and descent.

The leading wires which convey the current from the dynamo machines to the lamps consist of strands of copper wire coated with gutta-percha. With the exception of London Bridge these conductors are laid for protection in earthen pipes, which run continuously to the furthest lamp. Those crossing London Bridge are provided with an outer sheathing of iron wires and rest upon the broad ledge of the parapet. At the foot of each post is placed a cast iron box, in which the conducting wires from the lamp join those which come from the machine. The electrical generators, and their steam-motors are situated in the basement of a warehouse in Old Swan Lane. With a view to provide against possible accidents, the generators are divided into two equal groups, each of which is driven by a 60-horse power nominal steam-engine by Messrs. Marshall, Sons and Co., of Gainsborough. A third steam-engine of the same power is placed, as a reserve, between the other two, and so arranged as to be able to drive either set of generators, when their own engine requires clearing. In the room over the engines are placed the instruments for measuring the current and for switching it from either dynamo machine to either lamps, and other accessories. Here also indicators are provided so that the electrician in charge can see at a glance if the machinery is working regularly.

Such are the details of two out of the three systems of electric lighting which by their inauguration last evening mark the commencement of the largest and most important experiment in Electric Lighting that has yet been carried out in London. It is to last for a year, and the streets are to be illuminated by the aid of electricity all night, thus entirely superseding gas. The district allotted to the Lontin system comprises Southwark Bridge, Queen Victoria Street, Queen Street Place, and part of Queen Street. This light has taken the place of the Jablochkoff, and was to be in operation by the 31st ult. The lengths of streets covered by the various systems, and the cost of lighting, are as follows:—The Brush system, 1698 yards, at a cost of £1,119; the Siemens system, 1521 yards, at a cost of £3720; the Lontin, 1703 yards, the cost being £2930, the same as was to have been paid for the Jablochkoff light. The total cost of the experiment will thus be £7600—but the expense of gas lighting for the year will be saved. It will be observed that there is a considerable difference in the cost of the three systems. According to the figures furnished, the lighting by the Brush system will not exceed in cost that of the old lighting by gas, the sum to be paid to the Brush Company being fixed upon that basis, viz., £666, an amount which it is stated, will leave a very substantial working profit if the lighting is carried out upon an extensive scale. The total to be paid as above for the year's work, inclusive of installation, is £7416, as compared with a total of £2930, to be paid for the trial of the Lontin system, and £3720 for that of the Siemens system, over an approximately equal area. It will be interesting to see, therefore, whether the lighting by the Brush Company, upon the commercial principle of competing with gas in price, and at same time affording an increased volume of light (the only practically useful result to be attained by these experiments), will commend itself to the public sufficiently to ensure its general adoption. With regard to the appearance of the illumination itself we can only say that it forms a splendid electrical display, the pains being unquestionably carried off by the Brush light. We cannot, however, say that we regard the appearance of the lanterns and some of the standards with feelings of unmixed satisfaction, but when we get the best light fully developed in practice it will perhaps be time enough to criticise its accessories.

METALLURGY AND MINING.

Large Make of Steel.—Messrs. Bolckow, Vaughan and Co. have recently produced in one of their large pits the enormous make of over 1700 tons of Cleveland steel, which is probably a larger make than has been turned out of a single pit working an hematite in England.

The Future of Iron.—The following passage, taken from an article on "Dephosphorisation in the Converter," by M. Wahaul, late manager of the Creusot Works, in one of the Valenciennes Steelworks), which appears in the current issue of the *Revue universelle des Mines*, deserves notice, as showing the views of a practical man on the immediate future of iron. M. Wahaul observes:—"Those who are occupied in the manufacture of Bessemer steel know how difficult it is to obtain with regularity the extra soft steel employed for boilers in the French navy. Such metal appears to be made in the Martin furnace, and even then it was necessary to employ picked material in its manufacture. But by the new Thomer dephosphorising (Thomas-Gilchrist) process the same extraordinary degree of softness can be obtained with ordinary material, and at a price less than that of ordinary rail steel. By treating a pig containing from 1·5 to 2 per cent. of phosphorus, we obtain, after the blowing and dephosphorisation is finished, a non-oxydised metal which does not contain more than traces of carbon or manganese. If it be desired that the steel should be entirely free from any tendency to red shortness, we may add from 0·25 to 0·30 per cent. of a rich ferro-manganese to remove any traces of oxygen dissolved. Ready precaution to be taken to obtain a soft steel is to charge pig (if direct working be employed) which contains sufficient manganese (with 2 per cent. as a maximum) or to make a judicious mixture of pigs if capable be employed. But this will be by no means the only outlet for dephosphorised metal, for up to the present time the high price of soft steel has been the obstacle which has prevented many people from employing it in connection. But, by the new process, soft steel can be produced at a less price than ordinary (puddled) iron; therefore, therefore, no longer any reason (apart from routine) why steel should not be employed in place of iron, to which it is so much superior in strength."

ELECTRICITY AND TELEGRAPHY.

A Third Electrical Exhibition.—We learn that Vienna is to have its exhibition of electricity in the coming autumn. A committee has been formed, under the presidency of Count Hans Wilczek, and the Austrian Board of trade has offered the committee every assistance.

Electricity in Railway Travel.—Some important and interesting experiments in the application of electricity as the motive-power of trains have been carried on by Regnyi, on the section of the Eastern Railway of Hungary, between the Tzeyo-Szt-Peter Paths and Gerie. All the trains in carriages were provided with electrical intercommunication and the continuous brakes were worked by electricity, while all the compartments were lighted by electric lamps.

Domestic Electric Lighting.—A lecture on electric incandescent lamps suitable for domestic lighting was delivered in the concert-room of the Crystal Palace on March 15, by Professor Silvanus P. Thompson, of University College, Bristol. So far back as 1841 the attempt had been made to convert little electric lamps by enclosing in glass on the passage of an electric current, grew white hot. This method of procuring light from electric currents was revived in 1845 by Mr. Edison, who at first attempted to construct platinum lamps, which—however, in spite of many ingenious contrivances to protect them from over-heating—could not be kept from fusing up. Eventually Edison, employing carbon filaments in carbon, but not before a similar experiment had been made by Mr. Swan, of Newcastle. Edison arranged his filaments in the bamboo fibre, Swan from cotton thread. In each case the carbonised fibre was fixed in a small glass shaped globe, and exhausted as perfectly as possible of air by a mercurial air-pump. A filament of carbon thus treated became an elastic coil. Similar lamps had been constructed by Lane-Fox and by Maxim, with slight differences of detail in the manufacture. These little lamps gave a light of about equal brightness to one bright gas jet. They were destined to work a revolution in domestic lighting, would not only be cheaper than gas, but would be far more readily managed and kept in order. There was no unhealthy vapour or products of combustion produced, very little heat, no sound, and no risk of explosion. The incandescent lamps lent themselves with extraordinary facility to the purpose of decoration, and would doubtless rapidly become favourite modes of lighting. The experience of the theatre showed that it was practicable to apply them to large buildings. The public safety demanded that no fire be lost in making the electric lighting imperative in all theatres and public buildings. It might also to be made compulsory to use electric lamps in coal mines. The experiment would

Iron — June 1, 1882 — Iron — May 20 1882

Cost of Gas and the Electric Light.

Some additional data as to the relative cost of street lighting by electricity and gas are supplied by the new contracts for lighting New York, which have just been concluded. The price to be paid for gas lighting for the closely inhabited part of the city, in which by far the larger portion of the lamps are located, is $17·50 per year per light. In the outskirts and sparsely inhabited districts, from $19·50 to $22 per gas light is to be paid. The use of the electric light will be continued in portions of Broadway, Fifth Avenue, including certain parks and squares, in all a length of about six miles, at 79 cents per night per light. Arc lights are used by the Brush Company, also by the United States Company's styles. Each electric light displaces six gas lights. The contract price for each electric light amounts to $223 per year per light, which is rather more than double the cost of gas in the chief parts of the city. It is conceded, however, that the quantity of light furnished by an electric lamp is much greater and better than that yielded by the six displaced and dingy gas lamps. The streets that are illuminated by the electric light present an attractive and brilliant appearance. Reckoned by quantity of light supplied, the arc lamps are far cheaper than gas. Not so, however, with the incandescent system—the Edison system, for example, which is not at present used for street lighting in New York. Each small Edison light, not quite equal in force to an ordinary gas light, costs rather more than gas.

The Electric Light at the Reform Club.—The electric light is now being tried in two of the principal rooms of the Reform Club, in Pall Mall, with a view to its ultimate adoption. The new dynamo machine invented by Lord Elphinstone and Mr. Charles W. Vincent is being used with fifty Woodhouse & Rawson incandescent lamps. The new light shows off the rich gilt decorations on the walls and ceiling of the reading-room with much effect; and this was increased last night by fixing the lamps upon a crystal chandelier and using ground glass bulbs for the lamps. The motive power is supplied by an Easton & Anderson 3-nhp engine, dating from the building of the club, but which has long been put aside in favour of a high-speed horizontal. Nevertheless, on this occasion it is found to work well.

Iron — May 20 1882

The Electric Light in Sweden.—Besides the lighting of the royal palace in Stockholm by electricity, the chief dockyard at Carlscrona, the Portsmouth of Sweden, is supplied by means of Siemens machines. The motive power is furnished by a 60-horse engine feeding 30 Siemens incandescent lamps. The light is also now being introduced at the dockyard at Brunswerke, in Dalarne, the largest in Sweden. Two lamps of 3,000 candle-power each will light the dry docks and the military station, while two others of the same power will light the principal buildings; 100 incandescent lamps, 6,000 candle-power, will be used for lighting the interior of the engineering works. The total power of the light employed here will thus be 18,000 candle-power.

managed, through a highly influential channel, to put the Directors' story into the hands of the Liverpool Shareholders before a point was referred to. He (Mr. Hart) had not been expressed, that until there was something like an able and powerful Board, not only for the undertaking, but also for the Company, there was little chance of success which the Company required in the law, it would be wrong to waste money in litigation. He (Mr. Hart) had a further point of opposition to deal with to-day. He observed would bring F. J

From - Dec. 7, 1883

ELECTRIC LIGHTING OF THE *ADELAIDE*.

THE steamship *Adelaide*, a fine passenger boat, intended for the Australian passenger trade, and built on the Clyde by Messrs. D. and W. Henderson & Co., of Glasgow, has just been despatched for Australia. As the steamer is specially intended for carrying passengers, her internal arrangements have received special attention, and amongst other improvements she has been fitted up throughout with the electric light, under the superintendence of Professor J. Jamieson, C.E., Principal of the College of Science and Arts, Glasgow, as consulting engineer. The dimensions of the *Adelaide* are—length, 370 feet; breadth, 40 feet 6 inches; depth, 27 feet 6 inches; with a gross tonnage of 4,700 tons. She attained a speed of 14·9 knots at her official trial, and in every way reflected great credit on her builders. In the electric lighting installation there are 315 Edison incandescent lamps of 16 candle-power each, and four lamps each of 100 candle-power. The 16 candle-power lamps are disposed about the ship as follows:—20 on the awning deck, 73 on the main deck, and 42 on the lower deck and in the engine and boiler rooms. The four high-power lamps are intended for lighting the gangways and the spacious deck, when required for loading or unloading the ship, or for the reception or removal of passengers or luggage. The Westinghouse engine and dynamo employed for this purpose illustrated on page 761 of our present issue, is very compact and occupy a small space. They are placed beside the thrust shaft of the main engine close to the starting point, in order that the engine-room may easily attend to both. Besides this, the position being on the ship's floors, no noise or inconvenience is felt from vibration by the passengers. Extra precautions were taken by the consulting electrician to have large and well-insulated conducting wires, with the positive and negative wires carefully separated from each other by being encased throughout in wooden-grooved cornices, a precaution which unfortunately has not always been attended to, and to the neglect of which some at least of the failures which have attended some of the installations of electric lighting may be attributed. The lighting is not engineering, Limited, of 57, Queen Victoria Street, E.C. (whose address is Alley & McKellar, of Glasgow), consists of two cylinders C C, containing duplex pistons attached direct to connecting-rods, with their heads to lower ends, as well as the crank shaft to which they are coupled, working in oil inside the watertight crank-shaft casing C B C. There is but one eccentric keyed between the cranks (which are directly opposite to one another), and it works a piston valve, the casing of which is seen close to S P, the steam pipe, between the cylinders. This piston valve, by its up-and-down movement, admits steam alternately to the two cylinders, the exhaust, taking place near the end of the stroke through E P, the exhaust pipe. The engines are thus short-stroke single-acting engines. The steam is regulated by the stop-valve handle, S V H, and the governor, G. The whole engine, with its fly-wheel, F W, and shaft, S, is fixed on the same iron bed-plate, B P, as the dynamos, B, the whole resting on very strong and compact arrangement. The dynamo shown is one of the Edison-Hopkinson type, similar to that fitted on the *Tasmania*, but the dynamo used on the *Adelaide* was one of Edison's well-known L type. The different parts of the dynamo B may be described as follows:—S the dynamo spindle coupled direct to the engine shaft, A the armature (fixed to S) revolving between the poles of the dynamo, of which N S are the magnetic circuits, C C the electro-magnets, B the brushes bearing on A C the armature commutator, and C S the current switch. Each of the eight (fixed N S) revolving between the poles of the dynamo, of which N S are the magnetic circuits, C C the electro-magnets, B the brushes bearing on A C the armature commutator, and C S the current switch. Each of the eight (fixed with spindles 7 inches diameter and 5-inch stroke generated 22 brake horse-power with 90 lb. of steam pressure, and runs well at from 300 to 700 revolutions per minute.

From - June 29, 1883

THE MOSCOW ILLUMINATIONS.—The following are the details of the method by which the late fête illuminations at Moscow at the coronation were produced:—The towers of Iwan the Great and the belfry of Ivan Veliki had 3,000 small Edison lamps, fed by 18 accumulators, of which served a number of small electric machines of every existing system. The portable engines and machines were kept at the other banks of the river, and communicated with the towers by aerial electric conductors. The towers of the Kremlin towards the river sight large and ten smaller electric suns threw their light over the river. The rest of the illuminations consisted of 200,000 lamps and 30,000 coloured glass globes, 50,000 lanterns of Venetian glass, 600,000 taipers, and 10,000 lb. of fireworks.

From - June 29, 1883

ELECTRIC LIGHTING AT HEVERSHAM PALACE.—The ordinary method of illuminating the hall-room at Heckingham Palace has recently been superseded by electric lighting on the incandescent principle with excellent effect. The success, in fact, has proved so great at the recent state ball and concerts that it has been decided to continue the use of the electric light for the remainder of the season. It can well be imagined that the brilliant effect obtained in the hall-room places greatly in the shade the ordinary methods of illumination adopted in the adjacent supper-room and other parts of the state apartments. Steps are therefore now being taken to extend the electric lighting to these portions of the palace, which will then equal the hall-room in point of brilliancy of illumination, instead of appearing somewhat dark, as they are now said to. The arrangements are still of an experimental character, and portable engines only are in temporary use to drive the various dynamo machines required to produce the current for the lamps. Nearly 1,000 incandescent lamps have already been fixed, and all the arrangements are very complete so far as they go. Over 4 miles of wire, about two-thirds the cost of gas, but he was sure that it would be found to be the cheapest light in the end, and not the whole of the work with the assistance of Mr. W. Massey, consulting engineer, of Twyford, who has charge also of the electric lighting arrangements at Windsor Castle.

From - June 21, 1881

THE ELECTRIC LIGHT AT BRISTOL.—After considerable dispute with the Bristol United Gas Company as to an advance which the directors of that company wished to make in the price of gas supplied to the city for public purposes, the Bristol authorities have made elaborate arrangements to test the use of the electric light in some of the principal thoroughfares of the city. The machinery and lamps of the Brush system have been selected, and the lamps were lighted for the first time on Saturday night last.

THE ELECTRIC LIGHT IN THE GENERAL POST OFFICE.—Arrangements have just been completed with the British Electric Light Company for the experimental lighting of certain important parts of the General Post Office, St. Martin's-le-Grand. The first series of the experiments will be conducted in the telegraph instrument galleries.

Expecting from 7/1884

ELECTRIC LIGHTING NOTES.

MR. RUTHSHAM, boilermaker, has just lighted his works by means of electric lamps, driving the dynamo from his works' engine. The work has been carried out most satisfactorily by the Rutshamel Electric Light and Power Supply Company, Limited.

From - June 1/1881

ELECTRIC LIGHTING FOR DOMESTIC PURPOSES.—Mr. Swan's new incandescent electric lamps are shown to-night in actual operation at the establishment of Messrs. Edmonstone and Co., of Newmarket. The main feature of his invention is that a large number of small lights, four of which are stated equal to the same number of 'dropper' gas burners, may be obtained from a single apparatus. The latest arrangement of a small thread of carbon placed in a moderately large globe from which the air is exhausted, while it is a variety of the invention that the small carbon threads are prepared in a manner which prevents them from being easily broken. The electricity was generated on the above premises with the aid of a 4-horse steam-engine, described. Seven lamps were used in four rooms. In one there were two lamps with pendent glass globes, burning very steadily, and emitting no heat at all to speak of, while by turning a switch or key they were easily extinguished and re-easily relighted. In another room there were three small lamps without globes, giving abundance of light for rooms of moderate dimensions. In a larger room than either of the others were seen about a dozen lamps with opalline globes, screened globes. Some of these globes concealed gas, and others electric lights, the two kinds being undistinguishable from each other without a close examination, the effect being to meet the objection so frequently urged against electric lighting of painful whiteness or brilliancy. It seems to be considered that for the present the orders given for the Swan lamps, including necessary generating apparatus, will be confined to large private houses, whether in London or the country, such lighting, except on an extensive scale, for taverns, being in fact a luxury for the wealthy.

From - June 3/81

THE JABLOCHKOFF LIGHT.—We are pleased to hear that the committee appointed by the Metropolitan Board of Works to consider the proposals for lighting by the Thames Embankment on a contract for five years at a reduced rate (4½d. instead of 5½d. per lamp per hour) have reported favourably, advising the Board, however, to limit the contract to three years. The number of lamps to be supplied is eighty, and the hours of lighting extended from sunset to sunrise. The report will be read at the Board to-day. This decision, after nearly nine years of experience, speaks well for the electric light in general, and Jablochkoff's in particular.

THE JOEL ELECTRIC LIGHT.—An exhibition of Joel's system of electric lighting was given last evening, at the offices of the Prudential Assurance Company, 142, Holborn Bars, where it has just been applied to the lighting of a portion of the company's extensive premises. The light, which is of incandescence, will be found fully described and illustrated in our issue for April 22 last. There are nine lamps, which are equivalent to forty-five gas-burners. They are mounted on brackets, and so contribute the light very equally through the office in which they are fixed. The Gramme machine for generating the current is placed in the basement of the building and is driven by one of the engines belonging to the company used for generating air for the pneumatic despatch tubes which are laid all over the building. Should the present trial prove successful, it is intended to adopt throughout the company's premises.

Mr. Scott. may 3/94

ELECTRIC-LIGHT COMPANIES' PROSPECTS.

SIMILARITY to the way in which we have already discussed the position of the Brush and Illuminating Companies as bearing on the prospects of electric-lighting generally, we now offer a few remarks on that of the Maxim-Weston Electric Company, as disclosed in the Report and accounts to March 31st last, a *résumé* of which appeared in our last week's issue.

Following the plan adopted in other similar cases, the Directors of this Company carry large amounts to the debit of profit and loss, as the result of diminished estimates of patents, stock, plant, machinery, and shares in other Companies; as also £96,245, net expenditure to March 31st, 1893. It is worthy of notice that the loss on shares issued at a discount, £20,625, is fairly faced, and charged also to profit and loss account, which on the other side shows £250,000 as the result of the sale of licences and concessions; the outcome, after also crediting £2,665 profit of the past twelve months, being a child having carried into the balance-sheet of £102,150, which will be met by the proposed reduction of capital from £200,000 to £100,000. After the alterations thus indicated, the assets of the Company in the form of machinery, stock, book debts, and cash amount to £264,945; the other side showing liabilities to creditors £1,650, and its capital account £100,000. Besides the above £26,845, the other assets consist of patents now valued at £70,000, and shares in other Companies (as 2s. 6d. per £1) £2,453.

With the general line thereby, the production of relations and of capital, for future operations, with plant in thorough working order, with important improvements in lamps, dynamos, &c., and with engagements related to about one-half, the Directors eager for the Company a successful future, and hope to be in a position to declare a dividend for next year. With regard to expenses for the past year, one economy, which the Shareholders will doubtless appreciate, has been the relinquishment of fees by the Directors, besides which we notice an item of £500 abated from the expenses to March, 1893, for fees written-back.

As on working account is published, the amount of business done during the past twelve months is not shown, nor can we form any idea of the per-centage of profit represented by the gross profit of £5,817, brought into the accounts as a guide to the probable result of future operations. The amount of £8,295 for machinery and stock appears to indicate but a small quantity of machinery in work still, and such as would require to be turned over many times in the course of the year in order to yield a sensible dividend. Not that we consider this no unquestionable value, long aware that an unnecessarily large stock-in-trade is often the bane of an otherwise prosperous business. The explanation of the smallness of this item may perhaps be found, to some extent, in the comparatively heavy amount of book-debts. The figures of the two items invite comparison with corresponding items in the balance-sheets of other Electric-light Companies; but after all, may perhaps be indicative merely of a particular stage of things at the date of making-up the accounts, rather than of their normal condition. With reference to past business, the Directors submit the receipts of testimonials from every purchaser of their installations, which have included the lighting of mines, mills, warehouses, docks, theatres, and private residences.

Judging by the information thus given, and by what we gather also from the Reports of other Companies, it would appear that electric-lighting is gradually advancing in public favour, at least for private establishments. Its more general adoption turns, of course, to a great extent on the question of cost, estimates of which, in comparison with that of gas, for lighting even a single establishment vary widely, say, 150 (12 c.p.) gas-burners or 60 (30 c.p.) electric incandescent lamps, make out a *prima facie* case greatly in favour of the latter, without taking into account the saving on the score of the attendants non-determinable in figures. But the real proof of economy is to be looked for not in estimation, but in the results of actual use. Such proofs should, we think, be by this time forthcoming.

It is in its general adoption for house-lighting that, in our opinion, lies one of the principal, if not the principal, uses of electricity as an illuminant. If supply Companies can see their way to the production of the electric light at a cost not exceeding that of gas, and will undertake the house-to-house lighting of certain districts on such terms as to satisfy householders who have hitherto been gas consumers, the advantages of electricity are so manifest—especially, as regards private lighting, on the score of health and comfort—that it appears its general adoption should follow as a matter of course, any accidental difficulties, as distinguished from essential defects or constitutional prejudices, which may at present form hindrances to its becoming generally available being dealt with and removed as speedily as may be.

Engineering - Aug

THE ELECTRIC LIGHT IN THE MECKENBACH MINES.—The electric light installation at the Meckenbach Mines in its once volcanic lifeless district in Rhenish Prussia, has now had a fair trial for more than three years and has proved a complete success. The expectation that it would both facilitate the operations and reduce the cost of working has fully been realised, and an extension of the plant is now being carried out. Messrs. Siemens and Halske, of Berlin, undertook the work, which was superintended on their behalf by Mr. Boddinghaus. An open working 2000 ft. long, 1000 ft. wide, and over 300 ft. deep, in which 300 men and 28 horses are continually occupied, was first to be supplied with the electric light. The part of the mine is excavated in steps, the horizontal terraces being provided with rails. Ordinary lamps in globes or poles were out of the question, as blasting operations continue throughout the day and the whole would soon have made havoc of the lamps. After several trials two powerful lamps, of 3000 candles each, were erected at the upper margin of the pit where they were fairly out of the reach of the projected stones; and reflectors were fixed to throw the light down upon the steps. To find the proper positions for these powerful lamps and to avoid too dark shadows caused some difficulty. But the illumination was finally rendered most efficient, and the open pit with the light playing on the whitish grey rock affords a fine spectacle. Many interruptions, even for short periods, such as those occupied in renewing the lamp carbons, would be dangerous, the whole plant is double; each lamp receiving its current from its D, dynamo. No blinds of any kind are required, and the safety of the miners has decidedly been augmented. It was formerly always necessary for the superintendents to see whether the loose mass resulting from the blasting operations had been properly removed, and frequent minor accidents arose from the debris falling down upon the miners engaged on the step next below. The work can now be controlled much better than before when petroleum lamps and hand lamps were in use. The cost shows a saving of about 5d. per hour in favour of the electric illumination. The satisfactory results obtained in the open working induced the company to introduce the electric light also in a the subterranean galleries. The new forms little conversions of sand and galena scattered all through the rock; the whole mass has therefore to be brought to day to be disintegrated and sifted, and the washing proceeds in parallel and cross galleries, which are constantly being widened until they become 80 ft. in width, and 70 ft. in height, by sometimes 200 ft. in length. The operations in the meantime would not require much light if there was not always danger threatening from loosened pieces of rock. Pitch torches were formerly employed to examine the bore holes and fissures round them after each explosion. It was a question whether the arc lamp could answer for this purpose in the smoky atmosphere. For the first experiments, arc lamps of 2000 and 1000 candles were used, with the positive carbon in the lower holder. The effect was brilliant, yet the light did not penetrate the white smoke cloud which collected at the upper wall immediately after the shot. But as the smoke settles within ten minutes, it was thought advisable to continue in this interruption of a few minutes, and to use smaller lamps of 250 candles, which proved quite efficient. Of these, there are ten in use with about 10,000 ft. of lead cable, the cable being partially elastic, as the lamps with their wires have to be removed when the blasting is to take place. The lamps were originally supplied with hexagonal lanterns with obscured glass to protect the eyes of the miners. The glasses were of course soon broken, but no complaints are said to have been made about the naked electric lights. The proprietors of the mine have decided upon an extension of the installation.

Engineering - Aug 17/94

ELECTRIC LIGHTING NOTES.

THE electric light formed a prominent feature in the city illuminations on the occasion of the visit of the Queen and Princess of Wales to Newcastle-on-Tyne on August 20 and 21. Three powerful arc lights, each of 2000 candle-power, were erected in different parts of the city, one of these was placed in the beautiful pastern tower of St. Nicholas' Cathedral, and was visible for many miles around. The light shining through the stone tracery threw dark shadows across the sky in the shape of a gigantic cross. The other two lights were placed in the principal streets, one of them being just opposite to the gas offices, where an extensive gas illumination was exhibited. All these installations were carried out by Messrs. J. H. Holmes and Co., electric light engineers, Newcastle-on-Tyne. The same firm has also lighted a Polytechnic Exhibition at Hutton, County Durham, for which purpose a number of forty-five Swan lamps and one arc lamp worked in parallel circuit from the same dynamo, with perfect success.

The managers of the Covent Garden Theatre have again adopted the electric light for this season's promenade concerts. The Maxim-Weston Company have supplied the installation, the work being carried out on their behalf under the superintendence of Mr. Hugh Watt, the managing director of the Company. The systems of this company are certainly well known, but that is to say, they range, and all reputable appliances. And incandescence lamps, and all reputable appliances. In the installation now noticing, the generating plant is situated on the ground floor basement of the Floral Hall, and comprises three Maxim and three Weston dynamos. The current from these machines is conveyed through 600 Maxim incandescence lamps, those in use being arranged in the auditorium and over the stage. The Weston machines could supply current to forty-five Western arc lamps; these lamps not given out a light equal to 1500 candles, actual. The positions of the arc lamps have been carefully selected, and give very fine effect, more especially in the auditorium and over the stage, while the Floral Hall is lighted by by arc lamps. The Maxim generator in outward appearances resembles its likeness. It differs, however, from the machine in the construction of its armature, and the method of coupling up the coils differs from that employed in the Gramme. The principal feature of the new Maxim incandescence lamp lies in the preparation of its filament by a new process just patented, which the company claim, gives 20 per cent. more light for the same power, than any other. The Weston arc lamps has long been known as remarkably steady in its action, and the simplicity of its construction renders it especially suitable for public illumination. Covent Garden is one of the largest theatres in Europe, and the cables employed in this contract amount to several miles in length.

Engineering 8 Aug 17/94

ELECTRIC LIGHTING NOTES.

THE splendid paddle steamer Olympe, lately built and engined by Messrs. A. and J. Inglis, Glasgow, and owned by the Messagerie Fluviales à Vapor of Monte Video, and intended for passenger service on the River Plate, was thrown open to public view on the evening of Friday, the 11th inst., when she presented in her beautiful and extensive and highly successful electric lighting installations, might be inspected. The Olympe is a sister ship to the Sabrina which was sent out to the River Plate a number of weeks since, and the contract for which the electric light installation is the same as the one in that vessel, although a little more extensive as regards the number of lamps. In all there are about 330 Swan lamps of 20 candles power each, which are distributed throughout the whole of the vessel. The electrical current is obtained from an Elwell-Parker and Vincent dynamo capable of working 600 such lamps, and power is provided by one of the ship's main engines (we've high-speed engines of 40 horse-power. The most important novelty in this installation is the use of 45 secondary batteries which are placed in the engine-room, and which, it is said, are capable of supplying light to 50 lamps for a period of twelve hours, when the vessel is in port, or when the engine is at rest. So far as we are aware, this is the first time that an electrically lighted ship has been provided with accumulators or storage batteries in addition to the dynamos. Messrs. Woodhouse, Rawson, Limited, and Co., have been contractors for the installation.

On Tuesday, the 10th inst., judgment was given by Lord Kinnear in the Court of Session, Edinburgh, in the action of the Aylsham Electric Light and Power Company (Limited) *v.* Howard and Wyndham. The pursuers sued the defenders, who are the proprietors of the Lyceum Theatre, Edinburgh, for the sum of £226 5s. 6d., as the contract price of supplying and fitting up an installation of machinery and fittings for electric lighting in that theatre. The gist of the defenders' it was stated that they agreed with the Electric Carbon Storage and Apparatus Manufacturing Company of Scotland (Limited), for the furnishing of an installation of the electric light, at the price of £3262. In the event of the apparatus working satisfactorily, which the same should be ascertained by certificate under the hand of Charles Johnson Spencer, Kent, London, the defenders, according to the agreement, to grant a bond for January 31, 1894, for payment to the pursuers of £1000 on the expiry of twelve months; but if payment of the work proving unsatisfactory, such a bill was not to be granted. The Electric Carbon Storage Company having gone into liquidation, the pursuers agreed to take over the contract for supplying the theatre with the electric light. On February 11, 1894, Mr. Phipps reported that the work had not been properly completed, and the defenders pleaded that they were not entitled to pay the price until the defects were remedied. The pursuers refused to be reason payment on the principle of *quantum meruit*, for work done and materials supplied to the order of the defenders. The defence was, that the work was done under a special contract, the conditions of which had not been performed, and therefore the pursuers were not entitled to recover payment. The case was led at the end of last session. In giving judgment in the case on the 10th instant, Lord Kinnear held that the question for consideration was, whether the defenders' letter of December 1, 1893, was a binding upon the pursuers, he accepted as one bound by the contract which he thought it was. He then in the course of employment, he was the builder for them in the course of employment, he was the builder for them in the course of employment, he was the builder for them in the course of employment, he believe that he had authority so to contract. In these circumstances, his lordship thought that the defenders were justified in relying upon the contract by Mr. Monk; and if the pursuers were, in his opinion, therefore barred from denying that it was not in keeping with the expressions of that agreement. He thought that it was proved that the installation had been worked satisfactorily, and that it was not defective; that it was worse than useless for the purpose. Sir William Thomson had made an inspection, specifies of the installation, and in evidence that, for its part, he would not have accepted it for a single evening, supposing he had been contracted to light up the theatre for such evening. In his opinion, it would be better to have gas or proper for the defenders to light up the theatre for a single night. The result of the defender's finding was that, if the pursuers' claim was rested upon contract, the defenders were entitled to reject the installation as defective, and if it was rested on the ground unlimited at the bar, that the defenders had taken the benefit of work done without any antecedent contract, he was of opinion that they had taken no such benefit and had incurred no liability by permitting work to be done upon their premises which turned out unsatisfactory. He therefore assoilzied the defenders and granted them expenses.

The Globe, Toronto, Dec. 1, 1883

THE EDISON LIGHT.

On another page will be found a description of the installation in THE GLOBE building of EDISON'S system of incandescent electric lighting. The Globe is the first of Canadian newspapers to adopt permanently the new method of illumination. The light has been on trial for a time sufficiently long and under sufficiently searching ordeals to entitle us to speak positively as to its advantages. We have no intention in saying this to sit easily. Elaborate wires strung on water-power is already in use for the incandescent light can be substituted for it with economy, and with great advantage to the health and eyesight of the persons who have to work under it.

INCANDESCENT LIGHTING.

The Edison System as Applied in the "Globe" Building.

THE PROPERTIES OF THE LIGHT.

How It Is Laid On and How Run.

THE "GLOBE'S" ENGINE ROOM

The Dynamo-Electric Machine—The Mains —The Lamps—Their Power and Life—Other Installations in Canada.

It is now about six years since W. A. Edison, the well-known inventor of the Grand Trunk Railway, startled the world by his announcement that he had solved the problem of the subdivision of the electric current, and so had made the question of electric lighting a practical one. From discovery to discovery Edison went on till about two years and a half ago he opened in the most densely inhabited part of New York City, his first central station, whence his incandescent light was distributed to customers in the adjacent offices and stores. A representative of THE GLOBE was present at the opening of that station. He was struck an enthusiastic account of the virtues of the new light, stating that it was but a question of time, no matter what the cost of the light, when it would displace gas and all other illuminants in large establishments. From that day to this the cost of incandescent lighting has been steadily decreasing and the efficiency steadily increasing, until now there is

WITHIN THE REACH OF ALL LARGE ESTABLISHMENTS,

and it is to be hoped will soon be within the reach of the ordinary householder, a fact which is not very near perfection that only the most inveterate of anti-Edisons has any objection to offer. The incandescent light can be supplied at any power to which the engineer in charge chooses to run it. The light is absolutely steady. It has neural the glare or the flickering of the arc light. It shows colours faithfully, but—half it not in fault—it does not, as the arc light does, show up every little bit of soap or pearl powder as though it were laid on with a house painter's brush. In other words, the incandescent light is fitted for the hall or opera room, and for public assemblies of all kinds.

SMALL SCALE IMPROVEMENTS

which have been lately made in THE GLOBE Office, the Edison incandescent electric light has been placed throughout the building. The motive power for it is supplied by a fifteen automatic cut-off engine, which was introduced to the printing establishment a couple of years for the old water pressure engine which had driven the presses for a quarter of a century. The engine is of 35 horse-power nominally, but will work up to 50 horse-power. The cylinders are 14 inches in diameter, and the stroke three feet. The ordinary steam pressure is 60 pounds per square inch. This engine is one of the very best of its class, and is a credit to the establishment of which it forms a portion. It was manufactured by T. Wheatley of Guelph. A few days ago it was pronounced by a competent judge to be the finest engine in use in Canada. There is also an auxiliary engine which has lately been put into thoroughly repair by the above maker. It is a slide valve machine of 12 horse-power, with a stroke of 12 inches of cylinder and twenty-inch fly wheel. This engine is usually kept in reserve in case of the breaking of either, and is hardly ever used. When these new machines were being put in great changes were made in the engine room, and now that they are finished, THE GLOBE has one of the

MOST CONVENIENT AND WELL-APPOINTED ENGINE ROOMS

in the Dominion. The job printing department of THE GLOBE having been disposed of to the "Globe" Company about a year ago, the casting of the extensive plant for the latter, which had previously been occupied by the lithographing type and machinery, necessitated, of course, a good some important changes. The casting room was re-modelled and fitted up in a style worthy of the institution, and the rooms on the first floor underwent and improved. The front of the building was completely altered with the result of improving it greatly much. The most recent improvement, however, and by no means the least important, was the introduction of the system of incandescent electric lighting throughout the building. The arc light, that wonderful tool for street lighting, is protected by the completion of the electric circuit at high pressure through two carbons, whose points almost touch. The incandescent light is subdivided in

A MORE DEFINITE CURRENT

consisting of the circuit through a loop of fine carbonized thread, which looks like a very fine wire, and which has its ends attached to platinum plates, etcher, in which form it is put up, for economy as can be produced. The insulation of the carbonized thread under the influence of the electricity, excess with a soft golden light, pleasanter to the eye than either gas or electricity directly. There are 110 of these lamps distributed throughout the establishment. Each lamp is supplied by a Swan-light burner, with a candle power of 100 lights of 20 candles each. As a matter of fact, however, it is considerably more than that is needed for the 110 lamps in THE GLOBE building. The suggestion is the light of the machine is produced by wasting round the carbonized thread. The lamps are firmly attached through a great number of connections at copper wire, and are of the best form or manner, two and each, and are connected that one lamp is at each end of the other of a distributing. These lamps are hollowed out to a diameter of a little over $\frac{1}{2}$ inches. Between these recesses is a carbon filament of very fine paper and bowed to a separated by sheets of tissue paper and bowed to a horse-shoe form. Over these there is a winding of copper wire laid on longitudinally commencing at of 60 section of the carbonized thread with other and connected at the ends to

A COMMUTATOR

having an equal number of bars separated by mica. This commutator revolves at a speed of 1,500 revolutions per minute—power being obtained from a counter-shaft driven by the engine-room, running at a speed of 700 revolutions. The electricity flowing into the machine is generated in the armature in its own winding, passing by the bars "one the terminal turns generated and meeting the brushes which are connected to the field blocks, whilst on the other side of the fibre in the inside takes a direction through the magnet. On the commutator-armature—making a while two brushes—those one bar rest on each positive, and those on the other the negative. The current passes from the armature through the positive brushes, and, instead through the negative through the lamps, returns through the negative of the type known as

SIEMENS-HOUSING

has the strength required by a resistance placed in the circuit. The current may be cut off entirely being switch on the fuse-block, to which the leading wires are attached. These leading wires, a short distance from the dynamo, pass through a

"GALVANIC CUT-OUT,"

which is worked by the 35 horse-power. This is a most important improvement in case of excess of current, which it allowed to pass on through the wires might cause fire by overheating. If there should be an excessive current on the wire where it passes through the "cut-off," the lead wire therein would be melted and the circuit thus destroyed absolutely. The above-notice "cut-off" is the invention of Mr. Swan, and is finally constant, and is all composed of lead. The lamps are placed between the wires in what is know as "multiple arc," in contradistinction to the arc lights, which are invariably placed between branch in the wires or "in series," which therefore require an increasing electro-motive force as the number of lights is added to the circuit from the "mains" are also in "multiple arc." The rest of the branches throughout the building there are switches for turning on and off groups of lights when required. For instance, on the

LIGHTED INTERMEDIATELY AND EXTINGUISH,

the group for each room is independent of the others, so that as to turning the light on and off is concerned, this being regulated by a small switch, or key, in the centre of the room beside the lamp. Each lamp has a separate safety fuse, so that if one lamp should burn out it prevent the fuse should the wires of any lamp to any additional be crossed together or by those of any lights, or cause the fusing of a stretch of fuse-wire. The wire in the plug would in such case be instantly melted, just as in the "cut-off" at the dynamo, and the result for the lamp affected would be the same as at the dynamo. The fusing of the whole lamps would not be affected in any way. About 125 of the lamps are sixteen candle-power, and the remainder twenty are of ten candle-power. The lamps are of a very fine glass, specially made for the purpose, and which is exceedingly thin, otherwise the light would not be so powerful. The bamboo carbonized thread mentioned would work to extend before the entire surface had been warmed, would lead to frequent breakages. Within

THE PEAR-SHAPED GLASS

there is, as stated, almost a perfect vacuum. The air has been exhausted by a mercury pump until only the millionth part of an atmosphere remains. Each lamp has a guaranteed life of 400 hours, but it is expected that it will average 600 hours. The experience of THE GLOBE building this life has already greatly exceeded. The light was first started on 2nd November last, and has been used every working night since then. The lamps have thus burned about 600 hours, but only 7 out of the 110 have burned out. The life of the lamps has thus been 1,400 hours, and the remaining lamps are by no means dead yet. The shortest of bulbiferous, but, on the other hand, their life may be shortened to a few hours by accidents, and by frequently exceed that standard. The wires in the building are laid along walls or ceilings in wood moulding. From wall or ceiling to the lamp the wires are enclosed in a

HOLLOW METAL TUBE

like a gas pipe. The ornamental fixtures are much the same as are used for gas lighting. In the dining-room, for instance, there is a large group of lights in the centre, and others in various parts of the room, and in the main hall, the fixtures are exceedingly handsome. Over the type setters' frames and over the pressmen porcelain shades are used, which, instead of diffusing the light as would be required, because of the direction in which it is required, have a reflecting power. The general effect is much the same as gas, and many enter and leave the office without noticing that a change has been made, where the lights are not covered by glass or porcelain globes. However, the fact that the light is not diffused, but is instead of spreading out as gas does, is likely to add greatly to its economy. Those who have to use the light for any length of time find its superiority to gas in the

AMOUNT OF GLARE AND HEAT,

and its absolute steadiness. So far the lights have been used in THE GLOBE Office for the seven darkest weeks in the year. The result of this experience shows that allowing for interest on the investment, wear and tear of plant, extra coal, etc., the bill for light for the year will be less than it was for gas for the past year. Messrs. Gurney & Co., North Western Canada installation agents, under the superintendence of Mr. A. J. Lawson, the Manager of the Canadian Department of the Edison Company at Hamilton. Several other Canadian installations have been made in Canada. The following is a list of the places already supplied with the Edison light:—Toronto: Queen Street of the Canadian Institute, 100; Globe Office, 100; Canada Cotton Company's Mill, Cornwall, 1,000; Dominion Cotton Company's Mill, Valleyfield, 650; Canadian Sugar Refinery, Montreal, 350; St. Lawrence Sugar Refinery, Montreal, 250; Halifax Sugar Refinery, Halifax, 200; Canadian Pacific Railway Company's Shops, Montreal, 200; Tallman's and Co.'s Canneries, 1,200 and Guelph; McCulloch, Galt, 120; Gurney Building, 100; Grand North Western Telegraph Company's offices Toronto, 80. The lights in the last-named establishment are not yet running, but will be shortly. The force will be supplied by a dynamo of 1,000 lights. Other Canadian establishments being almost 100 last from each other. The current will be conducted over a copper wire the equivalent of an inch in diameter. This wire, like the smaller ones used within THE GLOBE building, has, for instance, a lead installation applied to the bare wire. Over this is a covering of vulcanized rubber, and over the rubber is a braiding. The whole being covered with woven cotton saturated with a special fire-proof paint, laid on under hydraulic pressure. The lamps, switches, lamps, sockets, and other accessories of the Company are manufactured in Hamilton by the Edison Co.

The Iron Age
Dec. 18, 1884

Electric Lighting on Railways.

An examination on behalf of the British Board of Trade was recently made of a train lighted by electricity on the London and Brighton Railway. Nearly six years ago, observes the London Engineer, the Brighton Company lighted up a Pullman express train by means of secondary batteries. The company have now adopted a combination of a dynamo machine, driven from the axle of one car, with accumulators. The advantages of this combination are very great over that of driving an engine and dynamo direct from the bolter of the locomotive. There is very little cost for power—perhaps a hundred-weight of coal in a journey of 50 miles. For some time a train then worked has been running upon the southern suburban line of this railway. The train has for the past month been running and now runs with a current of 40 ampères and 40 volts, which enables 40 incandescent lamps of 20-candle power each, distributed through the compartments of the train. The advantages of which means of this system of secondary lighting the train possesses is the automatic arrangement by which the dynamo is brought into action when the train has attained sufficient velocity to drive the dynamo at the requisite speed. In the present instance, as soon as speed of 20 miles is attained, a governor connects the machine with the accumulators, and the charging of the batteries proceeds, but so long only as this velocity is maintained. Provision is also made for reversal in the direction of the train by the same governor which shifts the brushes. No electrician attends this train, the plant being left in charge of the guard.

THE DETROIT FREE PRESS, WEDNESDAY MORNING, APRIL 22, 1885.

GOOD-BYE TO GAS.

The Edison Incandescent Light Introduced Into the "Post."

A Thing of Great Beauty, Brilliancy, Economy and Convenience.

The First Michigan Newspaper to Adopt the Edison Light.

The office of the Detroit Post are now lighted by the Edison electric incandescent lamp, which is the most perfect light in the world. The Post is among the first newspapers in the West to adopt the Edison system, and this is the only newspaper office in Michigan illuminated by the Edison incandescent light. In this respect, as in all others, the Post leads.

Of the Edison incandescent lamp too much cannot be said. The soft brilliancy of the light, its mellowness, beauty and convenience, are fit subjects for sustained praise. In comparison with gas the Edison light bears the same relation that gas does to a tallow candle, except that in the introduction of Edison lamps is unaccompanied by useless odors which affect the language and other organs of the body, breeding consumption and divers deadly diseases, as some gas is known to do. One might allude to the defect of coloring or the relief experienced in getting rid of a sickly, flickering, dispiriting light, with its concomitants of smoke, heat and dangerous flame.

WHAT A VISITOR WILL SEE.

Readers and friends of the Detroit Post are invited to call and witness the perfect working of a perfect light. They will find over each desk in the editorial offices, and over each printer's "case" in the newsroom, a pear-shaped bulb about five inches in length. Within each bulb is a loop of carbon gleaming at an apparent white heat, but the heat feels the bulb but slightly even when lit. The light is emitted steadily, constantly, without variation, and that gives out by each lamp equals in volume that of two gas jets.

THE ESSENCE OF HEAT.

Going into the newsroom, which is supplied with the Edison lamps, equal in point of light-giving service to twice that number of gas jets, the visitor will be surprised at the almost total absence of heat. With a like number of oil lamps or candles the heat would be quite oppressive. In the newsroom would be quite oppressive. In the newsroom there are 52 lamps, equivalent to 104 gas jets, and this is the only newspaper office in Michigan illuminated by the Edison incandescent light. In this respect, as in all others, the Post leads.

ELECTRIC LIGHTING NOTES.

UNDERGROUND CONDUCTORS FOR GREENOCK.

THE Electric Engineering Company have received the order for the underground electric light cables for the lighting up of several of the streets in Greenock under the provisional order obtained by the Police Board. These cables will be of three types, namely, the main cable, consisting of 36 strands of copper wire, 1.5 millimetres in diameter; the branch main, consisting of 12 strands of 1.0 millimetres; and the leads for the lamp-posts, consisting of 7 strand of 1.5millimetres diameter. These cables will be of the Berthoud-Borel type, insulated with Berthoud-Borel compound incased in a double sheathing of lead, the two sheathings being separated by a layer of gas-tar. A conductivity of 96 per cent. and an insulation of 1000 megohms per mile at the ordinary temperature are guaranteed. These cables will not be laid in any troughs or pipes. They will be layered end to end and in a layer or two sand placed in the bottom of the trench and the cables placed thereon. Another layer of sand will be placed over the cables which will be placed over and to indicate the presence of the cable to workmen afterwards taking up the street and save it from injury by their tools. Large quantities of these cables have time been laid in many of the principal Continental towns and give complete satisfaction. By this method of laying the Berthoud-Borel cables effect a great saving in time and labour in placing mains underground.

THE ELECTRIC LIGHT ON SHIPBOARD.

At the first meeting of the present session of the Institution of Civil Engineers, on the 11th of November, Sir J. W. Bazalgette, C.B., President, in the chair, a paper was read on "Electric Lighting for Steamships," by Andrew Jamieson, Assoc. M. Inst. C.E., F.R.S.E.

The author commenced with the statement, that, although it was not more than three years since the first ship was lighted by the electric light, and only two since the general illumination of passenger ships, the advantages arising therefrom had been so universally recognised, that none one hundred and fifty ships had been fitted with it, and scarcely a mail-steamer or a first-class passenger steamer now left the builder's hands without having it on board. This rapid success was mainly due to the following causes: 1. The electric light was a safe illuminant, even when properly fitted, was more luminous and cooler, more easily installed, and more actively than other modes of lighting; there was no smell, and no products of combustion to tarnish giltwork; it was more agreeable in every way than any of the other methods of illumination. 2. The danger from fire was less, as neither matches nor naked lights were required. 3. The daily cleaning and trimming of lamps was done away with, the keeping in order of highly inflammable oil, paraffin, or candles, and the greater cost so dispensed with. 4. The expense of maintenance was not much in excess of that of the other methods of illumination in some cases less, while the power required by the plant was not great, and its position was unobtrusive, so the engineers caused no annoyance to passengers.

As the dynamos which furnished the electricity for feeding the incandescent lamps had to be driven at a certain velocity, neither the ship's main engines, nor the donkey, for which engines were suitable for the purpose. The dynamo must have an engine for itself. It was, in most cases, necessary to have this special engine and the dynamo in such a position that the man on watch at the main engines could, from his station, see the dynamo, and attend to the electric plant. This necessary, therefore, was naturally somewhere near the starting platform. If possible on the ship's floor, so that noise vibration and noise might be avoided. Frequently a convenient position could not be found, either immediately behind the main starting platform or opposite to the thrust-block, but outside the engine-room casing. Only under such circumstances would it be at all desirable to lead the electric wires to the dynamo, its engine and attendant. In such cases a convenient and cool position was generally selected between decks, in the saloon compartment with a skylight over it, the refrigerating machinery, if any, being also found, so that one man might attend to both of these sets of machinery.

Where practicable the race of dynamos with large, heavy armatures should be placed fore-and-aft, so as to diminish as much as possible the effects of gyrostatic action, since the angular velocity due to rolling was practically constant. The author here gave Sir William Thomson's formula and examples, to show the pressure produced on the dynamo bearings, under different circumstances, by gyrostatic action.

In selecting a dynamo it was necessary to determine whether or not it fulfilled certain requisite conditions: 1. It must develop electromotive force sufficient to maintain a lamp when driven at a certain definite speed. 2. It must be self-regulating; that was, the electromotive force within 5 per cent. of given speed must remain constant to the full number of lamps. It was preferable to have a slight fall in electromotive force as the number of lamps was reduced. 3. There must be no undue emission of sparks at the commutator brushes. 4. Low temperature, and 5. Economising

Harrisburg Independent May 2nd 1885

EDISON ELECTRIC LIGHT.

Successfully and Satisfactorily Introduced in Harrisburg Last Night.

BRILLIANT AND STEADY FLAME.

Illumination Soft and Diffusive in Effects.

FAVORABLE POPULAR ENDORSEMENT.

A large crowd congregated in Market, Third and Second streets last evening to witness the turning on of the Edison Incandescent Electric Light. It was about 7.30 when the dynamos and electrical machinery were connected. Notwithstanding unfavorable atmospheric conditions last evening and that an immense load was turned on for the first time the light was inaugurated under the most favorable auspices. It having been announced that the light would be turned on May 1 the careless of the house company would not allow the public to be disappointed. When it is considered that the light, so far as this city was concerned, is an experiment, that 2,000 lights had to be turned on without being able to test them, excepting with a battery, the success of the undertaking can be comprehended. The station starts with 2000 lights, a number of lights of any station previously started. It is due to the liberal policy of the company in the matter of free wiring, which will be continued until June 1st, after which time all the wiring will be at the expense of the consumer, as in other cities. For the above reasons it was not expected that the Electric Lights would be turned on without interruption or accident. The company however was most agreeably surprised to find that with but two or three exceptions the lights in every building burned. Owing to the absence of certain electrical machinery and want of time to connect the indicators, the system was in some cases unbalanced, the lights on one side of the system burning brighter than the lights from the other wire. All defects will be remedied in a day or two, when the lights will be in good working condition.

A large number of distinguished gentlemen connected with the present Edison Company, of New York, as well as many interested in the business from other cities were present. All expressed themselves as highly pleased and considered the starting a great success, especially under the circumstances. Mr. Edison was unable to be present last evening, but is expected soon.

The details of the plant have already been published in these columns. All the machinery, engines, boilers, etc., was furnished by the Foundry and Machine Department under the personal supervision of H. B. Hershey, Esq., Superintendent, assisted by Mr. Thomas Reese. The verdict of competent judges last evening was that they had seldom seen a more complete and thoroughly mechanical job. Mr. Ide, the inventor of the engines, was present to assist at the starting. Mr. W. S. Andrews, Chief Electrician of the Edison Company, assisted by Mr. Theron Byington, of Meriden, Conn., who put up the electrical work in the station, were in charge of the dynamos. Mr. Batchelor, of the Edison machine works, manufacturers of the dynamos, was also present.

The outside and inside wiring was under the immediate supervision of Mr. C. B. Story, of Johnson, Vt., as examination of which will convey an idea of the amount of work performed in three months. He was ably assisted in the inside wiring by Mr. W. H. Jacobs, an expert, of Circleville, Ohio.

The Auditor General's Department, the main building, as well as the House and Senate, are already wired, and the light will be turned on as soon as the outer line is built, about Monday evening.

The light will be all that was predicted for it—a beautiful mellow light, without glare or flicker, no heat or combustion of oxygen, to render the air impure, perfectly safe and instantaneously turned on or off by means of the key. If necessary, all the lights in a room can be controlled by a single key.

The Company was exceedingly fortunate in having the services of Messrs. Story and spencer, thorough and practical electricians, by whom the plant was erected.

The stock of the Company has all been taken, the stockholders working harmoniously together in their efforts to give the city a better light than gas. A vast amount of work had to be done in which they met with hearty co-operation from the citizens, with the exception of a few chronic fossilsize who are an impediment to any city and desire to obstruct all improvements, and who are mainly responsible for the slow growth of the city in the past.

It is the intention of the Company to run the plant as rapidly as possible. It is anticipated that another engine and set of dynamos will soon have to be placed in the station, as the capacity of the plant, 2,000 lights, is fully or altogether taken. Feeders will be run in different sections as the demand warrants. Foundations and bolts for two extra engines and four dynamos were built when the station was constructed. Surplus boiler power was also provided for. As soon as the plant has been working order the light will be on continuously day and night, as there are three engines.

The light is supplied on the contract basis, a rate for each for each lamp per month per year. The life of a lamp is 1,000 hundred burning hours, replaced at the expense of the company when burned out, when carelessly or accidentally destroyed at the expense of the consumer.

The company is purely a local one, composed of Harrisburg business men. The officers and directors are: President, E. S. Wallower; Treasurer and Secretary, John L. Begge; Directors, E. S. Wallower, Thomas B. Holst, Joseph Strouse, J. L. Paul, B. Cohen, H. J. Stewart, B. M. Neal, W. H. Eby, and H. A. Clark, who represents the Edison interests.

The entire plant, buildings, machinery and installation has been constructed in a first class manner and will reflect credit on the city. The investment approaches very close to $100,000 and is expected to pay a dividend the first year.

Harrisburg Independent May 9th 1885

The Electric Light.

Now that the electric light has come to Norwalk, possibly to stay, a few words of explanation may be timely.

It is proposed to establish a "station" where the latent heat of coal may be converted into electricity, which, after passing over wires, shall be reconverted into heat in the lamps in stores or elsewhere.

The essentials of such a station are steam boilers, steam engines, and dynamos, otherwise known as electric generators.

The consumption of coal is a chemical process, developing heat. This communicated to the water in the boilers converts a portion into steam which, conveyed to the cylinder, becomes the physical to move and the wheels to revolve. The belt from the driving pulley of the engine connects with the pulley of the dynamo, and revolves a cylindrical armature between the poles of a powerful horseshoe magnet.

The common horseshoe magnet, taken as a toy, is accompanied by a bar of iron which, when the magnet is not in use, is held across the two ends or poles of the magnet, and the boys call it a "keeper." Electricians call it an armature.

The armature of a dynamo is not a bar but a spool, wound with wire from end to end as the the boys wind a kite string or a fishing line. Now imagine the ends of the magnet until the arms are about half an inch in diameter and the arm correspondingly large, and place the spool wound armature between instead of across the ends of the horse shoe, and you have the generator complete, and electricity is generated. An armature depending on the speed with which the armature is caused to revolve.

One end of the shaft of the dynamo is bare, and on it rest the prongs, which collect the electricity. Those are joined to the copper distributing wires which convey the electricity wherever it is to be used.

The electric light wires are of copper because copper is the best available conductor of electricity, conveying it with the least waste or loss. Electricity in its passage produces friction in a greater or less degree according to the "conductivity" of the medium through or over which it passes. It passes freely over copper but carbon is almost a nonconductor, and often when resistance that it becomes of a white heat from friction when a current of electricity is forced over it, and the Edison electric light is produced by placing a carbon in electricity over a loop of carbonized lamicon.

The Edison "lamp" is a pear-shaped hollow globe from the interior of which the air has been exhausted, and the carbon loop within is protected from atmospheric oxygen which, if permitted to reach the carbon, would immediately consume it. Protected from oxygen, the delicate thread of carbon is not consumed at any heat. When you look at the "electric light" you see nothing but a thread or filament of charcoal heated to white heat within the bulb of a pear shaped glass.

There are numerous words used by electricians which will come into frequent use here if an Edison station is established in Norwalk. We give a few definitions. *Dynamo*: An electrical machine, composed of a horse-shoe magnet, an armature and a commutator. The armature has been defined above. *Commutator*: That part of the dynamo which collects the electricity from the armature and conveys it to the wires. *Incandescent*: heated to a white heat. *Carbon*: charcoal. *Ohm*: the unit of the measure of resistance to the passage of electricity, the same as a gallon is the unit of the measure of fluid capacity, or a pound the unit of the measure of weight. *Volt*: the unit of the measure of electric force or intensity. *Ampere*: the unit of the measure of the quantity of an electric current. *Indicator*: used are the Dynamometer, or force measurer; the Galvanometer, or load measurer, in some respects similar to a thermometer; the Galvanometer, or measurer of galvanic electricity, and the Electrometer, or measurer of Electricity.

The lamps are lighted or extinguished by means of "switches," which are turned by thumb pieces similar to those used to turn gas on or off. They simply connect or disconnect the outer wires when the current of electricity is passing. Turned "on," they complete the current to pass over the carbon; turned "off," the current passes easily over the copper wires.

Harrisburg Independent May 19, 1885

THE NEW ELECTRIC LIGHT.

Satisfactory Operation of the Edison Incandescent Illuminant.

ITS SUCCESS IN HARRISBURG.

Convenience, Safety and Comfort Combined With Steady Brilliance.

HOW, PRODUCED AND HOW SERVED.

The new Edison Electric Light turned on May 1st has been running successfully and without interruption, excepting during the day to enable the force of wirers to make connections. The business of the Company is gradually assuming a system. The few consumers who had not been properly wired and those who had connected, for an insufficient number of lamps have been very patient, and the usual unavoidable and unforseen details incident to the starting of a new station, as well as all defects are being ailiminated. The light will be turned on during the day shortly, and the entire system is expected to run smoothly. The light has been received with admiration on all hands and notwithstanding the magnificent quality of gas, never surpassed in this city, the difference is plainly discerned. Already the absence of heat, cleanliness of show windows, the convenience, and the absence of the match nuisance, are being realized and appreciated.

At the station crowds of curious and interested people sit the windows watch the movements of the beautiful machinery. The perfectly regulating ide engines run like sewing machines. All the parts are in harmony. The speed indicators show no variation from no load to full load, running at a speed of 300 and 350 revolutions per minute. The dynamos work harmoniously and clean, displaying the machinery and electrical apparatus to advantage. The fluted wood finish on all sides and in the ceiling adds to harmony with the rest of the building. The Harrisburg station is considered the finest and best room in the country and reflects credit on Harrisburg mechanics. The dynamos, regulators, equalizers, switches, bars and rods, are all objects of great interest, and the room seems more like a wizard's shop than burning gas. By touching the bars of steel the full current of the system can be taken into the system. A shock will be experienced, never sufficient to injure but varying according to the intensity of the subject. The Governor' room, reception rooms, and store rooms are all lighted in yellow glass and correspond with the engine room.

On the second floor, rooms from the ceiling, are numerous beautiful chandeliers showing the adaptation of the light. On the side walls are samples of various styles of brackets. All are controlled by switches which flash the light instantaneously and as quickly extinguish it.

Admittance is secured by passes from the officers or in company with a Director. No one but employes is allowed in the engine room unless accompanied by a Director. The rules of the station are strictly enforced, and no talking to employes is allowed.

Several short circuits have been caused by persons tampering with the sockets of the lamps and wires, causing the lights to be extinguished but no harm where the lights have been tampered with. There are people in every city who know all about a new business, and after several inquiries occur it is expected the company will be the way of experimenting, or what would be more likely, it is impossible to be harmoniously with the current, the experiences of many experience very freely shock. Painters, carpenters and others are also reminded not to come in contact with the street wires as the current will be in the wires at all times.

LIGHTING LIGHTING IN BOSTON

Successful New York Experiment Likely to be Tried in the Hub.

We hear excellent reports from New York regarding the newly-organized American Electric Manufacturing Company, which is already taking a very prominent position among the electrical companies, and the combination lately consummated between it and the Edison company is certain to give the allied companies very great prestige, which is certain to be materially benefited. It is said that steps are now under way to form a similar combination in Boston. The combination system created Holborn station in New York, in the vicinity of Madison square, for Edison incandescent lights and American arc lights on a scale far ahead of anything yet attempted in the way of electric lighting. For some time the Jamestown Edison station, better known as the "Pearl Street station," did not pay, but now that the mistakes in building have been overcome and the system perfected the station is found to be the most profitable of the kind in the country, earning 4 per cent. on the capital invested, viz., about $1,200,000. Now it is claimed that it can be duplicated for not more than one-quarter of that amount, so that a combined American-Edison plant is sure of a very prosperous business, with good dividends on the investment.

We learn that the subject of a large combined central station is also under consideration for Boston, and that an American-Edison company will most likely be organized to put in a plant somewhat similar to the Newport plant yet in. Another feature of this combination which is of particular interest to the people of Boston is the fact that underground conductors would be used, as before by the Edison company in New York, removing the objection to overhead wires. If the American company are successful, this reform in the business will find the people of Boston ready to lend their hearty support. Certainly, any movement which will relieve our streets of the unsightly mess of wires and poles ordinarily be commended by all citizens.

THE ELECTRIC LIGHT.

Different Ways of Constructing a Contract—Machinery on Hand.

The published statement that Comptroller Spicer will let electric light company forfeited fifty cents a night for each light not in operation at the expiration of ten days after the beginning of its contract, caused the persons interested in the electric light to procure a copy of the contract.

AN ATTORNEY WITH THE PURCHASE.

An attorney has examined the contract and specifications in the case of the Jackson Arc company and this warning: "There is nothing in the contract or specifications that can be construed as a penalty of forfeiture until the company shall have begun operations, and then only for that portion of poles and lights not in use. The company is to have a reasonable time to do this. The gentlemen who have purchased stock in the company are satisfied that there is no forfeiture on the part of the new company. Mr. Spicer caused the examination to be made, and he is satisfied with it. Parsons is a long pole purchase, and Mr. Parsons nothing in these lists to charge his company a little to the property at Liberty and River streets is being investigated, and I presume it will be found all right. The transfer of machinery and other details of the enterprises will be carried out in accordance with the statements already published in the Times."

THE OSTRANDER VIEWS.

The contract with the Troy Gaslight company was executed April 20, and is for one year. The company is required to furnish 100 arc electric lights, or as many as may be ordered, according to the specifications, each burning six hours per night. The coming campaign of the specifications provides that fifty cents shall be deducted from the contract price for each light not burning each night. This, the committee say, takes effect from the date the company began operating one light, or at the expiration of ten days after the execution of the contract.

THE CITY ENGINEER'S VIEWS.

City Engineer Fuller is required to locate the poles and lights, and see that the work is erected, and that everything is done in erect the poles. When asked to-day if the forfeiture provision in the specifications is now in operation against the company, Mr. Fuller said: "Not at all. The specifications provide that the forfeiture shall begin after the electric light company is entitled to a certain time in which to secure machinery and erect poles."

NEW MACHINERY.

The new machinery received consists of two dynamos with a capacity of 100 lights! As soon as the examination of poles is concluded the company will immediately carry out all the requirements necessary to fulfil the contract.

N.Y. Herald

The Electric Light and Plant Growth.

A correspondent of the *Scientific American* recently discussed in that journal some evidence showing that the electric light is productive of plant growth. One of the best known florists of New York states that plants grown for decorative purposes in rooms electrically lighted seem to have all the health and vigor of plants under the light of a conservatory. This opinion is fortified by the observation that the flowers of Camellias and roses develop better on the mantel at nights of winter than on those in which there is no moonlight.

Fortunately for the interests of florists the effect of the electric light on plants has been scientifically traced in some degree. In 1880 Dr. G. W. Siemens made a series of experiments, the general result of which was that plants kept entirely in the dark soon died; those exposed to the electric light only or to daylight only threve about equally, and those exposed both electric light and daylight threve far better than either. Dr. Siemens exhibited to the Royal Society the specimens of the several plants upon which he experimented, which fully demonstrated the correctness of his deductions, and before his audience placed a pot of budding tulips in the full brightness of an electric lamp, the buds in about forty minutes expanding into full bloom. The evidence subsequently offered by Dr. Schübler, of Christiania, that plants under the continuous light of the Norwegian "midnight sun" develop more brilliant flowers and larger and more aromatic fruit than under the alternating influence of light and darkness, greatly strengthens the theory that the electric light may be profitably employed in horticulture. Observation shows that diurnal repose is not necessary for the life of plants, for in the northern regions of Scandinavia, where the summer is so short and the sunlight almost uninterrupted, vegetation flourishes except when chilled by boreal blasts from the Arctic Ocean.

The public, as well as florists and horticulturists, would be deeply interested in experiments made by the Department of Agriculture to determine the conditions under which the electric light might be advantageously and economically employed in forcing the growth of garden and hothouse plants.

To Electric Light Williamsburgh.

Electric-light poles are being placed on Bedford avenue, from Division avenue to Grand street, by the Municipal Electric-Light Company, which are to have on the poles, each, 1,200-candle-power lamps. When a moonlight night is caused by the absence of gas, the contracts to the Municipal Company will be void. The poles are placed 150 feet apart, and the lights 17 feet above the pavement. The poles are placed on the curbstone next to the sidewalk, and the contract calls for 100 lights. It is the understanding that experimental lights will be put up on Bedford avenue, and if satisfactory the poles will be placed on the other avenues mentioned. If the lights are satisfactory the poles may be extended to the Boulevard, and to the following streets in the Eastern district: Fourth street, Fifth street, Bushwick avenue, Broadway, Franklin street, and Manhattan avenue.

A RAILWAY RUNS BY ELECTRICITY AND IS NOT BLOWN UP.

The contractors for the Stanton and Barber railroad have decided to adopt electric motive power. The street car "accelerator" is the obstacle as to climate, etc., of which so much has been said. By this means they intend to construct the road during nighttime, when the temperature will be such as Europeans can withstand with tolerable ease, while during the heat of the day they can take their rest.

To carry out this arrangement a firm of Leeds, England, have already supplied two complete installations for electric lighting.

The engine, boiler and dynamo for each set, as well as the supports for the lamps when not in use, are all neatly fixed on a specially designed light railway truck. When in use the lamps will be hung from iron tripods 30 feet in height, and placed at intervals of 30 yards along the line of the proposed railway. These tripods are made of light iron tubing jointed at the top and made telescopic in the middle, so that they can be folded together, removed and united wherever required with the least possible trouble. The insulated cable to convey the electric current to the lamps is coiled on reels, two being supplied with each installation. On these reels the cable can be run off or wound up, as required. The lamps, which are of 2,000 candle-power each, can also be lowered forward, one at a time, from one end to the other as the work of reconstruction proceeds, a convenient arrangement being provided for the cutting off of the current from any particular lamp without interference with any of the others. The dynamo machines are of the Brush type and are driven by Parsons's patent high-speed engines. The boilers are of the locomotive type and are coupled by means of a feed pump with water from a tank fixed under the dynamo machine, which latter, by the means, is also kept cool during work. The cutters of the lamps are arranged to burn for a period of sixteen hours.—*Iron Age.*

Graphic - May 21/85

In a recent instructive essay on "Electric Lighting," Mr. Mattieu Williams, F. R. A. S., incidentally alluding to the cost and price of illuminating gas, says:

I refer more particularly to the practical and oriental question of economy. So far as economy, and consequently price, is concerned, the electric lighting interests have been developed with a power and skill furnished by the achievements of modern chemistry and engineering, which the gas-makers vainly try to meet by the utilization of the waste products of the gas itself as a volatile, magnificent coal-tar fuel. It would speedily and practically burn itself, and thanks to scientific bye-laws, is thus rendered harmless. Its value is so great that in less than nine months in London at one shilling per 1,000 cubic feet, if gas makers were compelled, as they ought to be compelled, to utilize it, it would be a considerable commodity and would subject us to a lucrative stimulating influence of free competition and private enterprise.

This is the language not of a dyspeptic but of a clear-headed, respected and dispassionate scientist. I therefore declare that the London companies merit confiscation for their extortion. New York solicits a much milder measure of protection against the tyranny of the meter.

Commercial Gazette (Cincinnati)
Sunday June 21st 1885.

GAS VS. ELECTRICITY.

[From Minneapolis Tribune.]

I was extremely obliged for the very excellent report of the interview which the Tribune printed upon the above subject. Mr. Herrick gave me a pleasant hour, and I only wish he might stay in town.

Mr. Herrick says—the interview was compiled in describing the process and progress in gas-making, the value of the residuals, and the various industries now dependent on gas products. I did not refer to another very important matter, however, well worth mention—the steadily increasing demand for gas in heating and cooking, and the gas engine. The day when gas-stoves will be in general use is not unnecessarily far good authority at the present. William Sinclair has affirmed that the day is not far distant when coal for domestic use, except cooking, heating and cooking will be entirely discontinued in our cities, and gaseous fuel will take its place. He argues that the expense and trouble consequent on the use of coal for household purposes is enormous, and that the cost of heating by gas on an at 1,000 cubic feet does not cost at per ton. Gas can be shut off after using it until it is continuous. Gas consumes itself to the point of consumption. Coal must be handled by the shovelful. There are over twenty thousand gas engines in operation. The electric light says nothing to gas in many ways, but the best power for running a dynamo. In a city like Minneapolis it is not a question of ability to light it, but it will be a necessity in it, at 3d dark and midnight. The curious is the use light are primarily made from the carbon which accumulates in gas-making retorts, gas-tar and the immediate by-products by burning the heavy oil of coal-tar. By the way, the here let me remark that no report of the last private lighting will ever be a success which does not include a description of the valid agent in illuminations, the electric light. Daily expenditures for carbon may be small, but were accounted annually it forms, with the manual labor of replacement, a formidable item. Incorporation of the electric light company for each are light.

Mr. Herrick advocates clubs; that where one-half dozen or more, the additional cost of lighting is not appreciable. Minneapolis has already tried it—has to get something better than has been accomplished. As to application of the Edison Incandescent Lighting System for a corner of Pearl and Third streets, No. 7, which I have frequently visited, suffices to say that I cause the Edison to be "successful and nothing" in the way of dividends. The "successful" is due to the steadiness of the generator, to the steam superintendence of various stations for eight years, and the economy has never paid one cent to the organization, four years ago, but sold. The Weil system (improvements and installations) was based than in 1882 a six-percent. dividend. Mr. Herrick says "original." As there is not an instance on record in this country or Europe, where an arc or incandescent company, paying a dividend for lighting such as is paid a dividend, it is fair to assume that, with the capital by increasing in price, the electric light stocks, before we will wait a long time to get "something for nothing."

The illumination is simply power, reduced to light, or, more simply still, under the same boiler-power in a gas engine, burned at the carbon point. The Otto Silent Gas Engine of the Centennial was run more economically, proportionately, than one burning coal, therefore saving an aggregate equivalent power. The subdivision of power always increases the proportionate cost. But in the subdivision of the electric current the light given by twenty arc lights of a thousand candle power is not so great as is represented in a single light, therefore, when the current is subdivided into the incandescent lamps or the largest, the 100-candle light (incandescent), the cost is increased by four times of 20 horse-power arc light, as seen in the streets of Minneapolis at seventy-five cents per night, is equivalent to paying for the same light from gas $5 per 1,000 cubic feet. Incandescent lights of the same power would, at the price charged for them here and elsewhere, be equivalent to gas at four 1,000 cubic feet.

Mr. Herrick says that Thomson-Houston people will, if asked, tell you that they can furnish that is given more light, a steadier light, a cooler light, &c. He will not tell you that it is arc-candle light, for however neat work, twelve the week after, ten in four weeks, and thousand hours, when the carbon expand on the interior of the lamp due to the oxygen which is never entirely eliminated. Neither does he tell you that these lamps cost you $1 each. Mr. Herrick says that the first current to burn incandescents was a larger one, and that now not tell you that these lamps cost you $1 each. He does not tell you that Mr. Edison himself —he of the "only original Aladdin lamp"—is often left to distance in his famous laboratory because the electric current won't do the incandescent burning. He never does thoroughly assert that. He will not tell you that nature's electricity, often, plays the deuce with Edison's, Brush's, Weston's, Thomson-Houston's, Fuller's, Swan's and Schuyler's currently. All who were present a year ago at the Coliseum on the occasion of the Thomson festival will never forget the terrible thunder storm—the lightning strokes—the extinguished lights—the almost frightful tumult—the total darkness—the shrieking women and trembling men. That very result is a commonplace in every city in the universe that is changing the mode of lighting its streets. To-day I interviewed the intelligent electrician of the West Hotel. He and an associate had charge of the Coliseum lighting. His colleague, who was near the dynamo, received a blistering stroke that left a mark down his shoulder, and one is crabbing and bent to this day. Since this party has retired from the electrical business, and is now engaged in what he added, "We always unharness the dynamo at the end of the day's run." But how about thunder-storms at night," I asked. He replied, "We still always executing an accident." In Chicago last week, during that terrific storm, the lightning destroyed an electric light, separated the wire, and left it in contact with wood work on a building in the center of the city, a fire resulted, and the whole block was in the ruins of the wires. The firemen were unable to get but not the same effect on the electric current of this sort, but it has an electric light stock; put until the manoeuvers were sent to the central station and the great dynamo shut off was the fire put out. At the same time by shutting down, it put out forty arc lights in hotels, saloons, restaurants and stores. During the great storm in New York, in 1882, never a light but that, except where the electric lights went out for a season less than a minute, are very unsteady, as are all arc and incandescent lights. It is the only unpleasant feature of this otherwise perfect establishment.

It is just as impossible to rent or write with, and steaming pitifully the eye sight, under an incandescent as an arc light. Since the introduction of the incandescent on the Fall River boats, reading is almost entirely ceased. It is unsteady as to flame, and trembles with the motion of the boat, and travelers complain bitterly. Even the Fall River railway depot in Cincinnati is ill, about with the incandescent, and complains of the same. I was there three weeks ago. It was quite table to read a newspaper anywhere except in the waiting-room and ticket offices, where the baggage and ticket offices, where all business is done.

The (so-called) 100 incandescent light, now abundant as sixteen-candle gaslights. Even in London recently the Duke of Sutherland installed the incandescent light in Stafford House, one of the great residences of the English aristocracy. The Edison Electric Company, and was placed on the best terms with the Duke, as a distributor. The experiment is over. He removed it after three months' trial, and soon he personally stated to me: "Too expensive cost. It's all he could have the electric light in my business." It is my opinion that the cost of three months' incandescent light is considerable's unreliability; it will set it at a good deal nearer hazard than any Detroit alderman will ever touch; but the people who pay the bills and who do not get any of the "dirt" would like to have it brought down to the street level for mortal use, leaving the stellar depths of space unlighted until the hard times are over, anyhow. In short, the electric light ought not to be stood at an altitude of more than twenty feet, and there ought to be at least two lights on each block. That is an improvement that will be worth something, and it must come.

THE DETROIT POST

O. L. STANDISH, Editor and Proprietor.

FRIDAY, JUNE 5, 1885.

THERE can be little or no question that electricity will give the light of the future, but the present method of lighting the streets of Detroit leaves the light altogether too far into the future. Detroit is well provided with the "contrivance of the dawn," it would like, just now, a little of the "dying" rose of Sharon." It may be important to squander nine-tenths of the light of good deal nearer heaven; than any Detroit alderman will ever touch; but the people who pay the bills and who do not get any of the "dirt" would like to have it brought down to the street level for mortal use, leaving the stellar depths of space unlighted until the hard times are over, anyhow. In short, the electric light ought not to be stood at an altitude of more than twenty feet, and there ought to be at least two lights on each block. That is an improvement that will be worth something, and it must come.

Why Capitol Lights Questions.

To the Editor of the Free Press:

There appeared a communication a piece of poor paper (Sept 26) on certain intended "electricity on Gas," which began the new series of a certain class of articles which will be found in the Free Press. Now, I am not going to say that the gas people will not from now right of date for their bills in particular upon their newspapers of the country, but I am sure that a certain number of them, if not a large number, will do what they have given the matter any thought. Now, I am not going to say that I am not a great lover of the electric light, but I am serious number of them, if not a large number, will do what they have given the matter any thought. Now, I am not going to say that I am not a great lover of the electric light, but I am serious enough to say that I am not a great lover of the electric light, but I am serious enough to say that I am not a great lover of the electric light, but I am serious enough

A RIVAL OF EDISON.

A very interesting séance took place on Friday last at the extensive workshops now in Paris of the well-known mechanical engineer and inventor, Bazin, who, in the opinion of the most competent electricians, has at last succeeded in rendering practically useful for domestic purposes, lighting by electricity, combined with small motive power.

The simplicity and completeness of this system puts it within the reach of all classes, and is calculated to produce results as remarkable as those which followed the accidental discovery of the power of steam by James Watt.

M. Bazin was highly complimented by all who witnessed his practical demonstrations and lucid explanations. Among those present we noticed M. Ferdinand de Lesseps; the Hon. L. P. Morton, ex-United States Minister to France; M. George Berger, the Director of the Foreign Sections of the Universal Exhibition of 1878 and President of the various International Electrical Exhibitions; M. Bapard, Chief Engineer of the Western Railway of France; M. Marcechal, Deputy; Mr. Walter W. Barker, of the U.S. Commission, and Member of the Jury of the Universal Exhibition of 1878; Baron de Gunhoung; Mr. H. E. Ellis, Mr. Morton's private secretary; and several professors of the École Polytechnique.

This invention is attracting the attention of electricians and others all over the world, and before long will be in practical operation.

* Temporary electric lighting is in use at the hotels in London, as it avoids the heat which even gas enables rooms. The loss of electric light is small, like concentrated sunlight, and its rural intensity is exerted by flooding trees and dewdrops with instruments that pick among the forms and leaves. In small glass globes of different colors, like thousands of jewelled flakes glancing among ferns and palms leave Aladdin's dream in the background.

Electric Light Notes.

Tuesday the Edison Electric Illuminating Company of West Chester submitted to the Borough Council a proposition, in which it was stated that they would light the town of West Chester every night in the year, and all night long, for the sum of $2,250 per annum. They would furnish 114 lights of 2,000 candle power each, and 25 extra lights. The proposition will be considered by the Council, and an answer given later. Last year it cost nearly $4000 to light the borough with gas for one night, and $14 a night to light the clock of the Court House. It is stated that the Edison Company will agree to use a test of the lights, and if they do not give as much light as represented, they will not be accepted.

Mr. Brookladay has rented a second-story room in Broughton's building, on High street, and has just moved from the Market House Station a number of electric lights, etc., to be used when the work of lighting the town is commenced. Orders for the lighting of residences would be judged that the light would be furnished by the Edison Company at the rate of $1.00 per month for the 64 candle power lights, and $1.50 per month for each 100 candle power light. The Edison Company is the invention of Thomas A. Edison, and is the largest electrical company in the world. The Edison Company is the invention of Thomas A. Edison, and is the largest electrical company in the world. The Edison Company is the invention of Thomas A. Edison, and is the largest electrical company in the world.

Electricians in Convention.

The first annual meeting of the National Electric Light Association has brought together in this city representatives of more than sixty electric light and electric manufacturing companies, and yet it is only a few years since the first electric light was introduced. The rapid development in the utility of electricity provokes astonishment, and yet electricians are confident that the developments of the next twenty-five years will be greater than those of the past, and the transmission of electrical power is regarded by many as a more important enterprise than the production of electric light, although the business is yet in its earliest infancy. A few years ago Bell offered the British government the exclusive right to use his telephone patents in Great Britain and the offer was declined; he offered about $2,000,000 for the same right and the electricians had their revenge in declining the offer. The circumstance illustrates the rapidity of the expansion in the value of electrical enterprise. Although there are more than sixty companies represented in the convention of electricians to-day, it is said that the stock of one of them is worth more than $5,000,000. When it is remembered what has been achieved with electricity since the first telegraphic dispatch was sent, forty-one years ago, and then considered that electricians expect the future to bring forth greater electrical achievements than those of the past, the imagination, faltering at the task of portraying the ultimate development of the utility of the earth's most mysterious force.

THE ELECTRIC LIGHT.

NOW IN FULL OPERATION AND READY FOR USE THEY OF ITS MERITS.

Ottumwa's electric light is now running full blast, giving ample opportunity to subscribers for a test of its merits. The light in use here is the Sperry system, controlled by the Sperry Electric Light, Motor and Carbrake Company of Chicago. The company is a new one and has made quite rapid progress, bringing their light in use in Chicago, St. Louis, Omaha, Grand Island and North Platte, Nebraska, Ottumwa and other points. In this city the company have placed two twenty light dynamos, which were started up about ten days ago and have been kept in constant use since that time. The light is clear, white and comparatively steady, a very important feature in an electric light. The engine used is of 50 horse power, manufactured by the Ottumwa Iron Works and the electric light company express perfect satisfaction with it.

W. S. Weston is in charge of the plant here—or as it is known by the company, "Ottumwa station." He is a courteous, affable and obliging young gentleman, and will serve his company well in the position he fills.

ELECTRIC LIGHTS.

The Western Company's Claim to Precedence Disputed by the United States Company—Some Historical Facts and Figures.

Some days since an article appeared in one of the morning papers under the heading of the Associated Press account regarding suits brought by the Edison Electric Light company against other corporations using an incandescent light. As the United states Electric Light company is probably the only one making a specialty of incandescent lighting throughout the west, its actions was apparent. This class of fore advertising has been used by the Edison company for years in a very large way, and their agent, upon seeing the article, got a good deal of benefit of what would be done in the future.

In getting at the facts in the case, Mr. Warren, the western manager of the United States company, was called upon for information in regard to these claims. In reply to the interrogatory, he said:

"We claim that the incandescent light *per se* is old, and that Moses G. Farmer, a well-known eastern electrician, as far as the distribution and subdivision of the electric current is concerned, used incandescent lamps twelve and five years ago that is used to-day. He at that time lighted his residence at Salem, Mass., with incandescent lamps. Mr. Farmer's patents controlling this feature of the electric light are owned by the United States company. We claim that we can supply the Edison people enough an infringement of these patents.

"Edward Weston, one of the ablest workmen in all dynamo-electric machines. He invented and procured patents for inventions, many of which were fundamental and of great importance. In 1878 he severed his connection with Edison and Mr. Weston's patents. A great deal of very important work was done by Weston here at Chicago, and the United States company has a large list of electric lighting or devices patented for any purpose. All of these patents belong to our company.

"Mr. Weston also did a great deal of work on the arc system, including early in the history of the art. It is not generally known that the first incandescent lamp which Mr. Edison claimed to have perfected, was made by Weston. It was in the early days of the use of the process of electric lighting, was invented by Kosloff. Edison was granted a patent, but Kosloff's claim was disputed, and the matter was settled by Edison purchasing Kosloff's patent and issuing to him, thus making Edison's control valid. This was the Kosloff-Edison patent. Mr. Weston's connection with the Edison company was very pronounced, and he went to England. Sooner says that the capitalists who purchased Edison electric lights were at that time not very favorably impressed with the company's connection with Weston.

"In fact," continued Mr. Weston's private secretary, "Edison's connection with Weston was such that he was compelled to leave the country. After securing Weston to take Edison's company's worth 50,000 pounds, he was compelled to buy Weston's interest, however, before the deal was finished.

"Mr. Weston has been satisfied.

"I will say that the incandescent lamps was old when Edison claimed to have perfected it. Mr. Farmer, who I have spoken to, has in his possession a number of small pairs of an electric light. Mr. Farmer has also a very complete set of patents for electric lighting, and we are confident that we will easily supersede any infringement that may be made upon our rights. We are almost irresistible particularly in the matter of the Edison patents, as we have the control of nearly every patent that has been issued to Edison, Weston or Kosloff."

The capital of this company is 500 and its incorporators are: Nothing are required to make a contract lighting number or which cover the incandescent system.

"The United States Electric Light company has been in existence for the United States about eight years. It was organized by Edward Weston and Edward Weston. These suits are based upon the claims of Edward Weston. Weston is a practical electrician, inventor, dynamo-electric machines, regulators, incandescent lamps, safety devices, etc.

"In connection with the Weston patents they had a large number of the most experienced engineers and electricians, many of whom have made this business a specialty for years. They have also employed a corps of experts in every respect to maintain their rights in every respect.

Some recent researches undertaken under the direction of Prof. Charcot, in his laboratory at the Salpêtrière, have attracted attention anew to a therapeutical agent which has been known for a long time, but which at the present time has fallen into disuse. We refer to the application of the magnet in the treatment of certain diseases. It is admitted by the believers in the efficacy of this mode of treatment that magnetization has fallen into discredit on account of the absence of precise rules for the application of the remedy, and also because of the air of mystery which seems to be connected with it. To Prof. Magdonal, it is said, is due the credit of calling attention again, in 1860, to the value of magnetic medication, and of endeavoring to establish it on a rational and strictly scientific basis. The first experiments were made at the Salpêtrière in order to verify the facts collected together by M. Burq under the generic title of metalloscopy. After the results obtained by metallic applications, it was natural to endeavor to throw some light on these phenomena by varying the conditions of experimentation. It was found that patients (especially those afflicted with nervous diseases) were not only acted upon by plates of different kinds of metals, but that like results were obtained by the majority of physical agents, such as weak currents, static electricity, sonorous vibrations, differences of temperature, magnetized bars, etc. It was soon found that magnetized bars were remarkable for the consistency of their action and the facility with which they could be employed. It is not claimed that magnets are endowed with specific properties, but that they form part of a group of physical agents which, in varying degrees, possess the same power as the above-named of affecting the nervous system and giving rise to biological phenomena. The Salpêtrière researches have provoked a lively discussion. The facts announced have been confirmed in Germany, Italy, England, etc., but have been boldly attacked likewise in the last-named country.

A medical writer in *La Nature*, who has been a witness of Prof. Charcot's experiments, says that the action of the magnet is in some respects so surprising that it might *a priori* excite mistrust. The application is not direct. The magnet is not placed in contact with the skin of the subject experimented on, but its action takes place at a distance. To influence the organism and to produce the same effects as with metals it only suffices to place the poles of the magnetized bar at one or two centimeters' distance from that portion of the body upon which it is desired to act. It is thus that all the experiments have been made at the Salpêtrière. It is not necessary that the magnet should be a large one, but merely that the magnetic force should be appreciable. It is alleged by the writer in question that this mode of treating disease should be ranked of equal value with other methods now in use, such as that of electricity, etc.

Effect of Magnetization.

It has long been known that a rod of iron when magnetized is lengthened; but recent experiments of M. Adér, formerly professor, who has so ingeniously investigated the origin of sounds in the telephone, have shed additional light upon the subject. M. Adér's experiments have led him to the important generalization that all bars of a magnetic nature submitted to a mechanical action, be it compression, tension, or torsion, tend to recover their primitive molecular arrangement under the influence of the current which magnetizes them. According to this principle if a coil is pulled out by mechanical action, the action of a magnetizing current is not to lengthen but to shorten it.

The remarkable induction coil recently constructed for Mr. Spottiswoode for Mr. Appa, and which gives a spark 42 inches in length, is described in last month's number of the *Philosophical Magazine*. We note that it has two primaries, either of which can be used at pleasure (for long or for short sparks). The one is of .056-inch copper wire and 660 yards in length: it has 1,341 turns wound singly in 6 layers. The other primary is 504 yards long, wound in double strand, forming three pairs of layers. The secondary consists of no less than 280 miles of wire, wound in four sections, the wire used for the central sections being somewhat thinner than those for the external section (the diameters are .0095 in., .0115 in., and .0120 in. respectively). There are 341,850 turns in the secondary. The condenser required proves to be much smaller than might have been expected. It is thought that if the insulation of the ends of the secondary wire were carried further than at present, a still longer spark than 42 inches might be obtained. From effects with a 28-inch spark it is calculated that the 42-inch spark would be capable of piercing a block of flint glass 6 in. in thickness. When used for vacuum tubes the coil gives illumination of extreme brilliancy and very long duration.

INDUCTION.

From the Royal Institution we have the original apparatus with which Faraday obtained the magneto-electric spark in 1831. It consists of a ring of soft iron, six inches in diameter, with two coils of insulated copper wire wound round it, each coil occupying nearly half the ring. When the ring was converted into an electro-magnet by passing a current through one of the coils, an induced spark was seen at the carbon terminals of the other. The Royal Institution contributes also Faraday's rotating rectangle for illustrating the inductive action of the earth, and other apparatus used by Faraday

ON MEASUREMENT OF THE ELECTRO-MOTIVE FORCE OF INDUCTION.

A session on the subject, by M. Donati, appears in a recent number of *Il Nuovo Cimento*. We have to note first the measuring apparatus, and next the experiments made with it.

The apparatus is a torsion balance, reminding one at once of that of Coulomb and of Thomson's electrometer; it appears to stand about midway between these two in point of sensibility. The points where there are differences of potential are put in communication with a condenser, which the author endeavoured to render as unvarying as possible; you then separate the plates, and put one of them in communication with the two balls of the torsion balance. From the impulsive deflection is deduced the charge, by means of a table of correspondence, obtained by examining previously to what initial deflections correspond the differences of potential (known by Ohm's law) of the different points of a conducting wire traversed by a constant current.

This apparatus then serves to verify, in open circuit and by electrostatic measurements, the already known laws of induction, viz., that the electromotive force of the induced current is proportional to the number of turns of the induced spiral (if all the turns may be considered as alike) to the velocity of the movement to which the induction is due, and to the intensity of the inducing current when the induction is electrodynamic. A pendulum carries, in its motion, the induced spiral; it is connected with an interrupter, constructed and used by M. Pellet, and meant to suppress, at a given moment, the communication between the induced spiral and the condenser. A particular arrangement serves at the same moment to measure the velocity of the movement. The charge of the condenser corresponds to the value of the electromotive force at the moment of the interruption. The author verifies, indeed, that with his condenser, and the circuit he employs, not more than $\frac{1}{1000}$ of a second is necessary for equilibrium to be established. In fact, the verification of the laws referred to is quite satisfactory.

M. Donati next studies the variation of the magnetism in a mass of soft iron serving as the core of an inducing bobbin. This core is not magnetized or demagnetized instantaneously; to the closure or opening of the circuit, and to the temporary variations of its magnetism, correspond proportional variations of electromotive force in the induced spiral. The latter is moved in the way mentioned above. The variation of the magnetism may be represented by an expression of the form—

$$K_1 a^{-ct} + K_2 a^{-c_1 t}$$

But this expression rather gives the sense of the phenomenon than shows its nature. The effect measured is, indeed, rather complex. Further,

ON THE INTENSITY OF AN INDUCED GALVANIC CURRENT.*

By HEINRICH LENZ[ETTE],
Professor of Natural Philosophy in the University of Helsingfors.

THE effects of an electrical current can be classed under two groups, one of which includes the galvanometrical and electrical results, and the other the electro-dynamical, thermal, magnetic, physiological, and purely mechanical. When a current of short duration passes through a galvanometer, it is well known that the effect is proportional to the quantity of electricity which is developed during the continuance of the current. If I is the intensity of the current—or the quantity of electricity developed in a unit of time, say a second—and t the time of duration of the current, then the effect, φ, is represented by the equation—

$$\varphi = k \int_0^t I dt$$

If, on the other hand, a similar current passes through an electro-dynamometer, the effect is expressed by—

$$\varphi = k' \int_0^t I^2 dt$$

These are the two characteristic formulæ of the above-mentioned groups; and if by means of them we seek to determine the intensity of an induced current, the total effect of which has been simultaneously measured both by the galvanometer and the electro-dynamometer, we obtain an expression for this which corresponds to the mean intensity of the whole current.

The case becomes different, however, if we interrupt the induced current for a short period of its continuance; we obtain then on the galvanometer an effect proportionate to the quantity of electricity which has been developed during the continuance of the current from the commencement to its interruption. If we continue in this way to interrupt the current repeatedly at unequal intervals, we obtain a succession of effects which represent the quantities of electricity corresponding to these different intervals. If i', i'', i''', i^{IV}, &c. denote the the mean intensity of the current, and t', t'', t''', &c., the corresponding intervals of time, then the effects are represented by the products $i't'$, $i''t''$, $i'''t'''$, &c. We arrive at this way at a means of determining and graphically representing the variations in the intensity. For if, taking co-ordinate axes, we set off the given intervals as abscissæ and the corresponding effects as ordinates, we obtain a row of points, the curve passing through which indicates the law of the quantities of electricity developed. Pursuing this train of investigation we obtain a series of values for the true intensity of the current, the variations in which can only be accurately represented by another curve, the abscissæ of which are the times t, and the ordinates the values of i.

Professor Lenzette has applied the above method to determine the course of the intensity of an induced current, his especial objects being to ascertain the influence which primary currents exercise upon an induced one, and the manner in which the latter behaves when the resistance of its circuit is increased, as is the case when a greenie of soft iron is placed in the induction coil. The following are some of the results of his experiments:—

1. *The opening or indirect induced current.* In the first half of the unit of time—that is to say in every second—the intensity indeed attains the maximum, but falls therefrom quite suddenly, so that at the beginning of the second unit it has sunk to a ninth of the maximum, whereupon the time-intensity curve runs asymptotically with reference to the axis.

2. *The closing or direct induction current.* The intensity of the current increases very slowly at first, but after about every second, a maximum is suddenly attained, whereupon just as suddenly—that is to say, within the same unit of time—it falls to about one-eighth or one-ninth of the maximum, in consequence of which the curve approaches the axis of x asymptotically.

When the resistance of the circuit of the inducing current is increased, the intensity is diminished, and the effect is at once perceived on the induced current.

When resistance is interposed in the circuit of the induced current, the opening current only indicates a marked decrease of intensity at the maximum, but the curve in other respects preserves its form. Under similar circumstances the intensity of the opening current increases somewhat, but with this exception, the curve remains as before. When the resistance is interposed in the form of a coil of wire, both currents show an equal intensity; the whole curve rises along the axis of x, and indicates a scarcely appreciable maximum for both currents.

When a greenie of soft iron is placed in the induction coil, the effect is somewhat increased on the power of the battery must be reduced, and then the intensity curve of the closing current is quite flattened away, but the opening current yields a curve which indicates the course of the intensity. It appears from this experiment that the induced current under certain circumstances develops an amount of electricity four times as great as that of the inducing current.

It is obvious that the results obtained by means of these experiments may be advantageously applied to elucidate the extraordinary electrical effects which have been lately produced with magneto-electric, electro-magnetic, and especially with electro-dynamical apparatus.

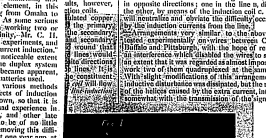
ON NEUTRALIZING THE EFFECTS OF INDUCTION BETWEEN TELEGRAPH LINES.

By CHARLES H. WILSON.

[Read before the American Electrical Society, Chicago, December 12, 1872.]

THE interference between well insulated telegraph wires, now universally known as induction, first manifested itself as a disturbing element, in this country, between wires extending from Omaha to Salt Lake, some few years ago. At some serious trouble had been experienced in working two or more parallel wires in that vicinity. Mr. C. H. Summers, electrician, made some experiments, and reported the interference to be "current induction." It did not manifest itself to any noticeable extent upon wires further east, until the duplex system was introduced, at which time it became apparent, probably on account of the large batteries used.

Since the introduction of the various methods of multiple transmission, the effects of induction have gradually become better known, so that it is now regarded by all who have had experience in working the quadruplex, duplex, and other late improved telegraphic apparatus, to be of no little importance. The possibility of removing this difficulty suggested itself to me about one year ago, at which time some complaints were made of difficulties in operating several Morse wires between Omaha and Sioux City. The ideas were carried out experimentally with good success; but, as it was possible to operate the above-named wires by having a "margin" over the induction currents, the arrangement was not considered of sufficient importance to be introduced. The theory by which the effects are produced, the conditions, however, which govern the action, and the manner in which the apparatus is applied to practical use, will be given in the following pages.



It was at once observed that having the two currents equal in strength was not the only essential condition requiring consideration. The *time* of the establishment of the two currents must be exactly the same in any section of the line where the neutralization is to be effected; otherwise, two currents, opposite in their direction, would be substituted for the single induction current, and they probably would not materially lessen the difficulty. After trying various devices to meet this condition of *time*, the most successful results were obtained by an application of electro-magnets. The artificially induced currents were made to pass through the coils of a series of electro-magnets, which, by their instantaneous magnetization of their cores, currents, and, by means of a rheostat, which formed a shunt around them, the proper adjustment was obtained. By increasing or diminishing the amount of resistance in the shunt, the prolonging effects of the electro-magnets can be adjusted at pleasure.

The application of this arrangement to "Morse lines" is shown in fig. 1: *c* represents an induction coil, constructed with two well insulated copper wires, with an adjustable core of soft iron; *a*, *a'*, *b*, and *b'* are electro-magnets placed in the path of the induced currents generated in the coil *c*, their function being to regulate the *time* of the neutralization of the two induction currents. The rheostats *n* and *n'* shunt the entire combination on either side. These shunts facilitate the essential adjustment of the opposing currents, and also lessen the effect of retardation, caused by the bullets, to the battery-currents.

Suppose the line *a* to have a battery at each terminus in the usual manner. On closing the circuit, two induced currents will be generated, flowing in opposite directions; one in the line *a*, directly; the other, by means of the induction coil *c*. These will neutralize and obviate the difficulty occasioned by the induction currents from the line.

Arrangements very similar to the above were tested experimentally on wires between Chicago, Dubuque, and Pittsburgh, with the hope of removing the interference which disabled the wires to so great an extent that it was regarded as almost impossible to work two of them quadruplexed at the same time. With slight modifications of this arrangement, the inductive disturbance was dissipated, but the reaction of the bullets caused by the extra current, interfered somewhat with the transmission of the signals. It

is well known that when an electro-magnet of any considerable size is worked in a line being worked quadruplex, serious difficulty is experienced in working through it.

In the quadruplex system at present used by the Western Union Telegraph Company, the condition of reversing the poles of the entire battery constantly occurs, and at each reversal there is an instant of no magnetism in the relays at the distant end of the line; and, as a consequence, the armature of the No. 2 relay has a tendency to yield to the force of the springs used to adjust over the "small end" of the battery. When the bullets are placed in the line, this neutral space becomes more apparent, and no longer would cause an interference if signals being transmitted in the same direction. The effects of retardation to reversals were less when the bullets were placed in the artificial line, than when in the actual line. This arrangement is clearly shown in Fig. 2.

It is evident that, with the "bridge" or differential principles, all that is required to affect the end in view is to cause the two artificial lines to act upon each other in a manner similar to the action of the actual lines. In the diagram, an induction coil is shown as a part of the artificial lines of the respective quadruplex arrangements, the two wires being well insulated, and wound side by side. The

Augmentation of the Induction Spark.—By M. C. M. Guillemin.—Everybody is acquainted with the experiment which consists in placing in the immediate vicinity of two coatings of a Leyden jar the extremities of the secondary wire of a Ruhmkorff induction coil. The length of the spark is reduced considerably, but the brilliancy and noise are, on the contrary, increased. I wished to see the effect of large insulated metallic surfaces, placed in contact with the two ends of the secondary wire, for the surfaces being separated from each other, so as not to produce the effect of a condenser. For metallic surfaces I took frames having each sheet eleven square feet covered with silk, and this with tinfoil. The coil there between two insulated points, which can be made to approach or recede from each other at will. So long as one or more plates of the commutateur with one of the poles only, the spark is in no way modified; but so soon as the other pole of the secondary wire is in contact with the plates of the other commutateur, the first, the brilliancy of the spark and the noise and its length diminishes. The increase of the surface produces a diminution in the brilliancy and the noise of the spark, and a new diminution in its length. If one of the metallic surfaces be greater than the other, the effect does not surpass that which two surfaces equal to the smallest produce. The effect of the plate becomes more sensible by the approximation of the points of the exciter, but if the distance of the points is reduced to a given minimum, the effect of the surfaces seems to disappear. When in place of the large metallic plates, metallic discs or rubbers of tinsel are employed, three-fourths to one inch in width, well insulated by means of glass supports or silk cords, we then obtain, by the use of equal surfaces, much more intense effects. Fifty-four yards of these metallic ribbons, placed in contact with each end of the secondary wire, making a total of 108 yards, greatly increase the length and the noise of the spark. The stronger the induction coil, the more marked the effect. In general the effects are the more intense when the insulated metallic surfaces are larger and separated from each other.

Practical Notes on Resistance Coils.

Ten coils, to be accurate, must be so constructed that the connections or plugs do not give appreciable resistance. The plugs should not be handled, except by the double handle intended for the purpose, because the adherence of a film of dirt or grease to the plugs would increase resistance.

The temperature of the bobbins should be uniform—best maintained by making the bobbins nollow and of large diameter, placing them all in one box. For small resistances long lengths of large gauge wire are better than short lengths of fine wire, as the former are less liable to derangement from a powerful current, and may be more easily adjusted. When the equal arms of a Wheatstone bridge are required always accurately at the same temperature, it is convenient to wind them on one bobbin.

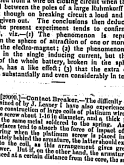
Prof. Fleeming Jenkin recommends that the wires should be insulated with two coatings of silk saturated with solid paraffin.

To avoid induction and magnetic effect the wire is doubled upon itself before being wound upon the bobbin, thus giving an equal number of turns in opposite directions.

There should not be any soldered joints inside the coils, owing to the danger of short-circuiting and break in continuity. Solderings with acid should never be employed.

Elect News July 8. 93

The Influence of Magnetism on the Extra Current. —A. Tolve.—Take an *electric egg* furnished with two small gold cups to the first a *thermometer* is fixed whose bulb penetrates to the centre of the egg, to the second an open-air manometer is soldered. The metal rod of the upper cup passes into a skin case, and is sided upon by a spiral spring that very rapidly returns it to its former position directly pressure is released. On applying the two poles of a large Ruhmkorff electro-magnet to the two cups of the egg, it was found—(1). That on producing the extra current *itself* the two poles of the electromagnet at the moment of breaking current, the thermometer regularly indicated 3° rise of temperature; so to the "mechanical" effect already noted by Rimsenley (in employing the *Sentenzie des Sciences de Paris*, last February. That paper explained how no noise nor spark is obtained from a wire on closing circuit when that wire is placed between the poles of a large Ruhmkorff electromagnet; though on breaking circuit a loud and violent noise is given out. The conclusions then deduced, and which the present experiments tends to confirm, were threefold, viz.—(1) The phenomenon is reproduced equally in the sphere of attraction of one or more of the poles of the electro-magnet; (2) the phenomenon is not inherent in the slight inducing current, but that the current of the whole battery, broken in the sphere of attraction, has a like effect; (3) that the extra current increases substantially and even considerably in tension.



Screw.
Contact Breaker.—The difficulty com-
plained of by J. Lower I have also experienced in
the working of platinum points of platinum wire for
the screw almost the same diameter, and a thick piece
of the same metal with the end of the spring. At first
surfaces tend to absorb the heavy deposit of the
mercury when the platinum screw is brought down
upon it, but by the slight vibration, the latter should extend
beyond, as this arrangement gives greater
power. Hard rubber, *Ebonit*, the armature is
placed at a certain distance from the core, the screw

should be about half-way up the spring (see sketch). It requires some experience to get the contacts perfect, however, and care should be taken to fix it firmly to the base-board. Foucault's mercury break is an improvement much in favour on the Continent for large coils. It can be worked either by the magnetism in the core itself or by a subsidiary battery and

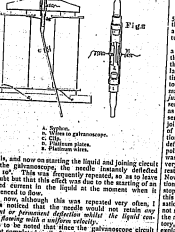
Decomposition of an Electrolyte.

battery was so Grove's cells, and the current through the magnet was led through a tangent galvanometer in the testing room in order to observe the constancy of the current.

The liquid used was dilute sulphuric acid, sp. gr. 1·24, temperature 18·2° C., and the resistance per cubic centimetre across opposed faces 1·7256 ohms at 20·2° C.

The tangent galvanometer used to detect the induced current was more delicate than that used in experiment 1. It was placed in an adjoining room far beyond the influence of the electro-magnet, insulated wires connected it with the platinum wires, sealed into the tube, and a current reverser, which served also as a contact breaker, and also a three out of circuit the electro-magnet's poles, and break the current under the same conditions as in (1). It was found that the rise of temperature accused by the thermometer does not ever exceed *one degree*; whilst the "mechanical" effect was never measured by a rise of the mercury column of more than 12 or 13 centimetres. Thus the interference of the magnetism manifests itself clearly both in a diminution of heat, and by a notable weakening of mechanical force.

Note.—This conclusion has been arrived at before by M. Tréve by a different method, as explained in a paper to the *Academie des Sciences de Paris*, last February. That paper explained how no noise nor spark is obtained from a wire on closing circuit when that wire is placed between the poles of a large Ruhmkorff electromagnet; though on breaking circuit a loud and violent noise is given out. The conclusions then deduced, and which the present experiments tends to confirm, were threefold, viz.—(1) The phenomenon is reproduced equally in the sphere of attraction of one or more of the poles of the electro-magnet; (2) the phenomenon is not inherent in the slight inducing current, but that the current of the whole battery, broken in the sphere of attraction, has a like effect; (3) that the extra current increases substantially and even considerably in tension.



20 cells, and now on starting the liquid and joining circuit with the galvanoscope, the needle instantly deflected about 20°. This was frequently repeated, so as to leave no doubt but that this effect was due to the starting of an induced current in the liquid at the moment when it commenced to flow.

But now, although this was repeated very often, I always noticed that the needle would not retain *any constant or permanent deflection whilst the liquid was found flowing with a uniform velocity.*

It has to be noted that since the galvanoscope circuit was not completed until after the magnet was made, this was not due to the mere induced current on making the magnet.

What was observed was this—after the first excursion the liquid, and shows that the decomposition by polarising the plates. But the rapid decrease of the liquid *carries away* the film of deposited gas on the plates almost as rapidly as it is formed, and so renders the polarisation but not great as it ought to be. The rate at which the polarisa-

swing continually approached nearer and nearer to the zero of the scale, so that within at first this point nearly 0 to the right, it dropped soon to 3°, 2°, 1°, and after a very short time, although the magnet's field remained constant and the flow uniform, the galvanometer needle was making nearly equal oscillations of diminishing amplitude on either side of zero. On stopping the liquid, the needle gave a very slight but sudden jerk in the opposite direction to that in which it first started. The full meaning of this will now be pointed out presently. This experiment, repeated many times without failure when once the difficulties had been overcome, gives an experimental proof that when an electrolyte flows in a magnetic field an induced current is set up, and that its direction is as follows the same law as is solid. The line or direction of the current is from one platinum plate to another, and this direction is at right angles to the line of flow or movement; the lines of magnetic force are at right angles to the plane containing the line of flow and line of current.

There are three things on which the success of this experiment depends:—

(a.) The plates must be *perfectly deposited* to begin with—so perfectly that when contact is made and broken, with the galvanometer in the breaks so as to fall in with the period of oscillation of the needle, still no movement occurs.

(b.) The platinum plates must be so fixed as to be incapable of making the slightest movement under the greatest velocity of liquid used, for even the otherwise tiny vibrations, by their movements, produce induced currents.

(c.) The velocity of the liquid should be rendered as uniform as possible, and the strength of the magnet's field also constant.

In the above experiment the velocity of the liquid was 56·9 c.c. per second; this was accurately by measuring the volume of liquid which flowed through in 35 seconds, and the velocity calculated from the dimensions of the tube.

Having thus obtained practically the induced current in a proving liquid, the next question was attacked, viz., is this electrolyte to be decomposed? To answer this, the platinum plates were again most perfectly deposited and the galvanometer disconnected, and the platinum plates short-circuited by joining the wires attached to them. The liquid was then allowed to flow down, the magnet being kept "made," and the circuit was opened *just before* the liquid stopped. It may here be observed that the liquid was never allowed to run out as far as to empty the syphon, but only drawn off from the reservoir down to a certain limit. The plates were then joined to the galvanometer, and there was no deflection of the needle of 2° or 3° to the right in the *opposite* direction to that in which the induced current would have deflected it when the magnet was made. This proved the polarisation of the electrodes to a certain degree, and this was confirmed by the fact that the liquid flowed down in very soon subsided; after a few moments it was again at rest at zero, and no further current could be detected. Now when I first tried this I obtained no opposite deflection on joining circuit with the galvanometer before stopping the flow. I was not altogether satisfied with this result, since sometimes I found no trace of polarisation, and at other times a very slight trace, which did not seem to increase with the length of time during which the acid was allowed to flow down. This was unsatisfactory, but a reflection this appeared to be capable of explanation, thus—as the liquid flows down in the field of the magnet, it is subject to induced current on cutting the lines of force. It can be worked either by the magnetism in the core itself or by a subsidiary battery and

On Electric Inductors.

The word induction, when used in connection with election electricity, refers to a peculiar mode of action of this agent, or which a vast number, indeed, we may say all electric phenomena depend. It is in fact only on account of the so-called inductive action that we do serve most electric manifestations, whether of attraction or repulsion, of charge and discharge, of positive and negative condition, etc. Therefore this subject is of the highest importance for the right understanding of the laws of electricity, and we will again devote a few experiments to it with the necessary to repeat practically, if one desires to possess a clear insight into the laws governing this most mysterious and interesting branch of physical science.

In order to make these experiments successfully, it is preferable to possess some form of electric machine, as described, page 232, however small, by means of which, on a suitable dry day, a sufficient electric charge may be obtained. The other instrument required is the electroscope, which every one may easily make for himself; this instrument is arranged in different forms, but all are based on this principle, that bodies charged with the same kind of electricity will repel one another. The most sensitive of these instruments is the electroscope of Bennet; it is represented in our fourth figure, and consists of two strips of gold leaf, suspended from the lower end of a metallic rod, terminating at its upper end in a ball of the same material; the gold leaves are enclosed in a glass cylinder, or bell jar, so as to be protected from air currents, and a metallic knob with two upright wires terminating in disks or balls, completes the apparatus. The latter serve to discharge the electricity from the gold leaves by contact, being so placed as to be touched by them, when the leaves diverge to their maximum extent. To enclose the gold leaves in a bottle, as is sometimes done, is very objectionable, as the inside of the bottle soon becomes dusty, and thus charged with electricity, and totally disturbs the indications of the instrument. Sometimes the two upright wires mentioned are replaced by two strips of tinfoil, pasted against the glass, and continued downward to the metallic base, so as to be touched by the gold leaves when they diverge far enough, and so discharge the electricity; this arrangement is equally good.

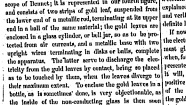


Fig. 1.

The first experiment to show the inductive action is represented, fig. 1. Let an insulated and positively charged conductor A be brought in the vicinity of another conductor, B, likewise insulated, but uncharged. If the latter be provided with two such ball electroscopes, suspended at each end, they will be seen to diverge more and more as the charged body approaches, and on examining the nature of the electricity which causes these balls to diverge, by means of a well rubbed rod of glass or sealing-wax, an explained page 232, it will be found that if the conductor A is charged with vitreous or positive electricity, the end of the uncharged conductor B, nearest to A, will have become resinous or negative, while the farthest end will be vitreous or positive. When the body A is discharged, the electricity in B disappears at once, and the inference is, that the proximity of the positive charge in A, destroys the natural or neutral state of B, and decomposing it, as it were, into the two opposite electricities, causes the same to become attracted to the two extremities of B, while the removal of A, or of the electric charge of A, restores these two electricities to their together, and neutralizes one another, or disappears.

It is even that also here the law prevails, which was mentioned on page 232, namely, that electricities of the same nature repel one another, while those of opposite nature attract. In this case it is not only the bodies charged with electricity that mutual repulsion, but the electric charges themselves: the portion of B farthest from A still above the same electricity as A, while the portion of B nearest to A will show the opposite electricity.

It is this clear that this body B is by no means charged with electricity by contact or communication of electricity from the body A, but that becomes electrified at a distance, by a kind of mysterious influence, which it has been agreed upon to call *inductive*. This word therefore offers no explanation, but is only the name for a certain class of phenomena, letting under the law just explained; all that we can do is to study these phenomenon, and verify that they always are manifested subject to the definite law of attraction and repulsion.

If now we apply this law of induction to the use of the electroscope, fig. 4, it is seen that this apparatus must give indications of electricity without contact; when, for instance, a rod of well rubbed sealing wax A is presented at a distance to the knob C of the electroscope, it will become in its condition, indeed, a positive electricity at the nearest upper portion C of the upright rod, while the lower end carrying the gold leaves will become negative like the wax, and the leaves will diverge by the negative charge. If the rod A is withdrawn, the gold leaves will again fall together and not a trace of electricity will remain; but if the knob C is touched by the wax A, then the whole rod from C to the gold leaves will be charged by communication with the negative electricity from the wax A, and retain the charge when A is removed. When the electroscope is in this condition, it is the best criterion to determine the nature of the charge of any electrified body; when it is charged negatively like the electroscope, it will, when brought in the neighborhood of C, cause the leaves to diverge more; if charged positively, it will, when brought in this neighborhood, cause the leaves to converge, as then the positive electricity leaves to converge, as then the positive electricity leaves to counteract or neutralize the negative charge of the instrument.

Fig. 2.

It is seen that by this peculiar action of electricity, bodies may be charged without that the body which causes this charge loses any of its own electricity. It simply induces the neutral body to manifest electric properties, and that only temporarily, as long as the influence lasts; therefore the term, electricity by induction is very appropriate and generally accepted.

If during this inducing action the body B, fig. 1, is momentarily touched with a conductor, so that the positive electricity which is repelled by the positive charge of A, has a channel to flow off. It will remain negative and this negative electricity will show itself as soon as A is removed from the vicinity.

THE ELECTROSCOPE.

We are now prepared to understand fully the action of the electrophorus and Leyden jar, represented in figures 2 and 3. AA, fig. 2, represents the section of a disk of sealing wax, or its equivalent, placed on an insulating stand, B; BB is a flat metallic cover or dish with an insulating handle C. When the wax disk AA is well rubbed and excited with negative electricity, the cover BB is placed on it, and the negative charge of AA will repel the negative electricity from the cover BB, and attract that of the positive kind, as indicated with the signs p or + and n or —. When now the disk BB, while laying on AA, is touched with the finger (which is a good conductor) this negative electricity escapes, and the positive kind is attracted in the cover BB; when then the cover is raised, by means of the insulating handle C, the positive electricity in BB will manifest itself by a small spark, when brought near a conductor, and by other manifestations of its presence, and this will verify that you always are manifested subject to the definite law of attraction and repulsion.

If now we apply this law of induction to the use of the electroscope, fig. 4, it is seen that this apparatus must give indications of electricity without contact; when, for instance, a rod of well rubbed sealing wax A is presented at a distance to the knob C of the electroscope, it will become in its condition, indeed, a positive electricity at the nearest upper portion C of the upright rod, while the lower end carrying the gold leaves will become negative like the wax, and the leaves will diverge by the negative charge. If the rod A is withdrawn, the gold leaves will again fall together and not a trace of electricity will remain; but if the knob C is touched by the wax A, then the whole rod from C to the gold leaves will be charged by communication with the negative electricity from the wax A, and retain the charge when A is removed. When the electroscope is in this condition, it is the best criterion to determine the nature of the charge of any electrified body; when it is charged negatively like the electroscope, it will, when brought in the neighborhood of C, cause the leaves to diverge more; if charged positively, it will, when brought in this neighborhood, cause the leaves to converge, as then the positive electricity leaves to counteract or neutralize the negative charge of the instrument.

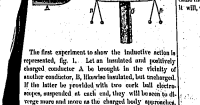

Fig. 3.

It is seen that by this peculiar action of electricity, bodies may be charged without that the body which causes this charge loses any of its own electricity. It simply induces the neutral body to manifest electric properties, and that only temporarily, as long as the influence lasts; therefore the term, electricity by induction is very appropriate and generally accepted.

If during this inducing action the body B, fig. 1, is momentarily touched with a conductor, so that the positive electricity which is repelled by the positive charge of A, has a channel to flow off. It will remain negative and this negative electricity will show itself as soon as A is removed from the vicinity.

THE ELECTROSCOPE.

We are now prepared to understand fully the action of the electrophorus and Leyden jar, represented in figures 2 and 3. AA, fig. 2, represents the section of a disk of sealing wax, or its equivalent, placed on an insulating stand, B; BB is a flat metallic cover or dish with an insulating handle C. When the wax disk AA is well rubbed and excited with negative electricity, the cover BB is placed on it, and the negative charge of AA will repel the negative electricity from the cover BB, and attract that of the positive kind, as indicated with the signs p or + and n or —. When now the disk BB, while laying on AA, is touched with the finger (which is a good conductor) this negative electricity escapes, and the positive kind is attracted in the cover BB; when then the cover is raised, by means of the insulating handle C, the positive electricity in BB will manifest itself by a small spark, when brought near a conductor, and by other manifestations of its presence, and this will verify that you always are manifested subject to the definite law of attraction and repulsion.

If now we apply this law of induction to the use of the electroscope, fig. 4, it is seen that this apparatus must give indications of electricity without contact; when, for instance, a rod of well rubbed sealing wax A is presented at a distance to the knob C of the electroscope, it will become in its condition, indeed, a positive electricity at the nearest upper portion C of the upright rod, while the lower end carrying the gold leaves will become negative like the wax, and the leaves will diverge by the negative charge. If the rod A is withdrawn, the gold leaves will again fall together and not a trace of electricity will remain; but if the knob C is touched by the wax A, then the whole rod from C to the gold leaves will be charged by communication with the negative electricity from the wax A, and retain the charge when A is removed. When the electroscope is in this condition, it is the best criterion to determine the nature of the charge of any electrified body; when it is charged negatively like the electroscope, it will, when brought in the neighborhood of C, cause the leaves to diverge more; if charged positively, it will, when brought in this neighborhood, cause the

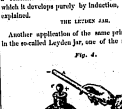

Fig. 4.

electric contrivances, named after the city of Leyden, Holland, where it was invented more than a century ago. It consists of a wide mouth glass bottle, covered with tinfoil, externally and internally, to within four or more inches from its opening on top. This top is closed with a stopper, through which a brass rod reaches to a metallic connection between the stopper and the interior coating; a perpendicular glass rod supports a brass ball, through which a stout brass wire also, reaching to two brass knobs, G K, with a curved brass wire, F, connects the outer and interior coating, or another brass rod, and by means of a chain, H, with the electric machine, which has to charge the jar with a sufficient quantity of the jar. The chain G connects it horizontal isolated wire with two knobs with the outer coating of the jar, as seen in H, which chain further is connected with the earth or any other large conductor; when now the inside coating of the jar is charged by an electric machine and the intervention of the chain F, with say positive electricity, the inductive agency will operate through the glass on the outside coating, and repel the positive electricity from there attracting the opposite kind or negative; this will flow then through the lower chain, from the conductor

Inductrial Coal.

[2217.]—I find such a mass of queries on this subject, as yet less than five addressed personally to me, that I think it better to concentrate the replies in one article, than to scatter the information in several directions.

[2218.]—The first part of this question as to the relative merits of long and short coils, I replied to a number or two ago (222 ff), p. 230. It is purely a matter of pitting cost effective results from a given quantity of wire and battery. A bundle of wires is better than a bar, because in the latter the interior convex core forms in the core itself, and this reduces the magnetic effect. The bundle of wires has a curved outside form to the wire bundle, because there is no result of solid metal. The terms quantity and intensity, as regards a cell or battery, are not identical. The first means the amount of chemical action, the second the electromotive force, or power to produce that action against resistance; but this is not the only meaning for a cell, it involves a reference to constancy of action.

[2217.]—Charging Jar from Coil.—This is to be done by using a discharger in the circuit to one of the coatings of an insulated jar—that is to say, there must not be complete insulation between the wire coil to the coatings, but there must be a break across which the spark will pass, and the charge not be lost; that is the only way of getting the current past. If there is complete circuit, the current will flow, and make needless such attempt, and there can be no charge.

[2217.]—The instructions as to primary wire given as p. 467, Vol. XX. One end is connected to a binding screw, and the other to the spring of the break. The binding screw for the battery wires should be at the other end of the coil. The length of the primary wire would take about from pennies No. 14, and from three to five pounds of secondary could be put on advantageously. If No. 14 is used, there should be from 4lb. to 5lb. spark produced with moderate battery power. Eight pence a wire about 1s gross per foot. What might be bought for that sum I cannot say.

[2218.]—If Mr. Williams will turn to pp. 382 and 430 of Vol. XX., being in Nos. 467 and 475, or to p. 382 of my book, he will find the information he requires given fully. He gives some special references to it, and so do I, as he has not my whole figure to refer to, and it is not mine. I cannot answer for Mr. Williams's results, but they are not primary at once, rather than the reverse, I think. The stress of fall he names would be too wide for his coil, as he ought to have a good spark round them. Their number will depend on the battery power he uses, and that upon the quality of the insulation. From 30 to 60 yards of electric will be about the [illegible].

Signed,

The Western Union Telegraph Company and the Ruhmkorff Coil.

THE Ruhmkorff coil, like the electric telegraph, is the result of a series of investigations which would not have been going on for the last fifty years, and in which at least a score of investigators have taken part with more or less success, according to their knowledge, information, disposable time, pecuniary means, or other resources.

In our March number for 1873, we have given a condensed history of the electric telegraph, showing it to be the result of accumulated investigation, of which no one man can claim the whole. We showed how for the last one hundred years, various facts had been discovered and many ingenious matches invented, the sum of which aided in further inventions, and how of some fifty prominent investigators, the work of each was important in reaching the final result. This was nearest reached by Prof. Joseph Henry, of the Smithsonian Institution in Washington, who can lay a better claim to the invention of the electric telegraph than Prof. Morse, who obtained the patent, and who only made use of what others had invented before him. It was for this reason that the patent claims of Morse were very weak, and would not have stood the test of a vigorous opposition were it not that they had been bought by a company organized on the basis of plenty of capital, who wanted to obtain the monopoly of electric telegraphy in the United States, and who, in order to cut off possible competition, employed the most eminent legal counsel and scientific talent which money could command, in order to sustain the claims of Morse before the courts and have his patents recognized as valid.

The facts however are there, which show the truth, and posterity will award Prof. Henry, not as the sole inventor, but as the man by the results of whose investigations Prof. Morse was enabled to do what he did. We refer the reader to the above mentioned article above referred to, which appeared in our March number for 1873, in which the facts speak for themselves. No statement made there can be denied, being based as it is on printed records of the dates mentioned.

The company which held the patents of Prof. Morse, which have long since run out and become public property, has been fused into a great stock corporation under the name of the Western Union Telegraph Company, and have now commenced the same game which they so successfully pursued during the period of validity of the Morse patents, namely, with a patent for an induction coil, obtained in April, 1868, by Prof. C. G. Page, of Washington, and under which this stock corporation is now suing the makers of such medical electro-magnetic apparatus as have the least resemblance to the induction coil. The latter has only become famous since Ruhmkorff applied to it such important improvements that it became an entirely different instrument, which is now known under his name, and for which he received a well-deserved award of 50,000 francs from the French government.

When Prof. Page saw the great results obtained by the Ruhmkorff induction coil, and the fame the author received for it, he petitioned Congress in 1868 to enact a special law to authorize him to apply suits and obtain patents for some inventions which he had applied for twelve years before, and which at that time had been refused by the Commissioner of Patents, on the ground of want of novelty, and he requested Congress to authorize the Commissioner of Patents to grant the patent to C. G. Page, all laws in operation to the contrary notwithstanding.

The Ruhmkorff Coil.

One of the most remarkable pieces of apparatus belonging to a modern philosophical cabinet, and at the same time the most fertile in exhibiting startling experiments, is the combination of two nearly independent and isolated coils, surrounding an isolated soft iron core. It bears the name of Ruhmkorff, after the Paris instrument maker of that name, who has the credit of first having ensured its general introduction, by procuring it at very moderate prices, for experiments and as a product of manufacture and trade, while at the same time he succeeded, by several improvements, in multiplying its power more than tenfold.

The late Prof. Page, of Washington, claimed to be the inventor of some of the details applied in this coil, as well as of the small so-called torpedo electric machines, used for medical purposes, and which in fact are diminutive and simplified Ruhmkorff coils; however it is well known that the main principles on which the effects of this coil are based, are the discoveries made about the year 1830 by Faraday in England, and Ampère and Arago in France. They discovered the effect of a current in one coil on another coil surrounding the first, while Arago invented a machine essentially the same as the Ruhmkorff coil. Notwithstanding this, Prof. Page succeeded in inducing Congress to grant him a grant for an invention he claimed to have made more than 28 years before, and almighty slow and difficult they were, in the face of numerous precedents and the power to do under the existing patent laws, and granted a patent to Prof. Page for the invention of the Ruhmkorff coil, which in fact for the last 30 years had become public property, as well as the small electric machines based on the same principle; during all this time they were furnished by the instrument makers to numerous customers. It was at first said that this patent was to be extended as an acknowledgment of the merits of Prof. Page, and notwithstanding he could not be considered as the discoverer of the principle, nor as the first or sole inventor of the instrument, no scientific found fault with this acknowledgment, as Prof. Page labored well of electrical science in general, having been one of the foremost investigators, especially in regard to attempts of utilizing electro-magnetic attractions as a motive power; these however he abandoned on experience taught him the erroneous theory that the power thus derived is more than the fitness deserve than that derived from coal by the intervention of steam.

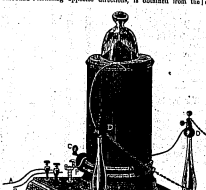
After Prof. Page's death, his widow sold the patent to the Western Union Telegraph Company, and they in their turn sold it to the Scientific American Company, who have since then commenced lawsuits against all the small and often struggling and poor manufacturers of small medical electric instruments, for damages for infringement of their patent, and a supply for the right to manufacture in the future.

We intend to contest this imposition to the utmost, and can do so easily by proving by official records, and the English Philosophical Transactions and the Memoirs of the French Academy, the utter invalidity of both patents of Prof. Page.

We believe this, even if Prof. Page were the first and inventor, the patent issued by Congress can have no legitimate power, and annul the right of public property obtained by more than twenty years undisputed possession, especially as no patent law guarantees the right of any invention longer than such a period of time.

The principle upon which this instrument is constructed is as follows: If two coils of copper wire, one over the other, are wound around the same hollow cylinder, and isolated from one another, and if then one of the coils, say the inner one, be made to discharge a voltaic current, another current of very short duration will be induced in the outer wire, both when making and when breaking the contact. This current is called a *secondary current*, and runs in the reverse direction when the contact is made, and in the same direction when the current is interrupted. The strength of this current is considerably increased when the hollow cylinder inside of the coils is filled with an iron bar, or better still, by a bundle of soft iron wire, as in this way the magnetism of the iron, by being alternately developed and destroyed, aids its influence to the development of the current in the outer coil, according to the principle explained on page 99 of our February number for 1873.

The closing and interruption of the current may be effected in different ways; in the machine here represented it is done by a contact-wheel, moved by a handle, and by a rapid motion of the arms a series of currents running to and fro, that is, in continually alternating opposite directions, is obtained from the



THE RUHMKORFF COIL.

shain attached to the glass insulators seen in front, and which are connected with the ends of the outer wire, while the ends of the inner wire are connected with the contact-wheel, and by the intervention of this wheel with the voltaic battery, (not shown in our engraving.)

So much for the principle of this remarkable apparatus, the further details of which we will explain in subsequent articles.

Cause of Cholera Infantum.

A practical physician of Berlin, Germany, has been investigating the causes of that horrible disease—cholera infantum—which yearly carries off thousands of beloved children, and one of the principal causes he finds in the patent nursing bottles, an American invention, which has reached Berlin, by reason of its convenient form. It consists of a glass bottle, which is filled with warm milk; through the cork of this bottle a glass tube passes to the bottom, and at the top of the glass tube is a rubber tube with a mouth-piece for the child. The physician referred to publishes the following remarks and advices: "The supposed advantages of these bottles consists in this, that they can be placed beside the infant in bed, while other bottles must be held in

ELECTRICAL STATIC REPULSION.

Present interest is from time to time being awakened in those grand celestial visitants of our system, shoals which there pass, month by month and year by year. The general phenomenon they present are familiarly known. Their enormous comets tails are apparent; but not less demonstrable is the extreme tenuity of the vapors or gases composing them; through which, in thick weather, small stars shine with almost undiminished brightness, and traversing rays of light suffer no perceptible refraction. It is further known that the sun has a powerful influence on this cometary matter; for the comets tend in a more condensed and globular form when at a distance from him; but, on coming nearer, the substance increases in lightness and volume, and alters in form, giving the phenomena of the tail, which is most extended in the perihelion, and, generally turned away from the sun, appears subject to a repulsive force exerted by him.

The question as to the nature of this force has not yet received a decisive answer from physicists, but there is strong probability that it is of electrical nature. This was the opinion of Olbers, and M. Faye's observation that the force diminishes with the square of the distance, and that it is proportional to the active surfaces, is in accordance with the hypothesis. M. Zollner's theory of electric repulsion between the sun and comets is based on the statical repulsion of two electricities of the same name. But there is an evident difficulty here, for the law of distance between two celestial bodies, like the sun and a comet, being too great for polar action to be possible, the action of the two electricities should neutralize each other.

The subject appears to have important new light cast upon it from a series of researches by two Austrian observers, MM. Holtlinger and Dibenfurt, described recently to the Vienna Academy. If a flagon or any conductor be brought near the luminous cushions in a Geissler tube, an attraction is observed, which has been explained by the known laws of electrical influence. But these observers, experimenting with a number of tubes, found some which gave a pronounced repulsion instead of an attraction. These cursy tional tubes contained, one bromine, the other perchloride of tin. Besides repulsion, the tubes showed a peculiar green light on the side towards which the column was forced; a kind of electric phosphorescence.

Examined spectroscopically, both tubes gave like spectra, and the most visible parts presented the three bands which are generally attributed to the spectrum of carbon, and which are not well in chemistry species. The identity of carbon is accounted for by supposing the that the light was not furnished by the gases that had been introduced, which may have been absorbed by the electrodes, or precipitated on the glass; but by a trace of some surface dust of another kind.

The authors then prepared a number of tubes with cyanogen gas, oxygen, hydrogen, carbonic acid, and other gases, examining the light in the manner used in all these cases for spectral attraction. But, on pursuing the rarefaction further, the effect was reversed; they obtained repulsion. This became more and more pronounced, so long as the rebulous light was not replaced by a simpler and stable sort of stratification, which appeared unfavorable to the effect. The light of the negative theophore shows neither attraction nor repulsion. The rarefaction was continued down to 0·2mm.

When one pole of the induction coil is connected to one of the electrodes of a Geissler tube, and the other pole connected to earth, the interior of the tube may be rendered luminous in three battery of eight elements was used. In this case there is marked attraction in gas having a tension of 6 to 8mm. Continuing the rarefaction, you come to a neutral point: thereafter the same gases give a repulsion quite as pronounced as the previous attraction; and it may even be observed at a distance of three to six centimetres. This repulsion always increased with the rarefaction, and it was the greatest possible with the greatest degree of rarefaction.

INDUCTION COILS. 1877

The largest induction coil yet made is that of the Royal Polytechnic Institute, of London. The length of this coil is 9 feet 10 inches, diameter 2 feet, weight 16 cwt., including 177 lbs. of best rubber. The core is 6 feet long, and four inches in diameter, of No. 16 iron wire. The primary coil consists of 145 lbs. of No. 20 wire. The secondary coil consists of 150 miles of wire, weighing 660 lbs., and having a resistance of 31,500 ohms. The condenser is in six parts, each containing 125 square feet of 12 inches in length, and with 20 coils this has been increased to 29 inches.

The induction coil constructed by Ritchie for the Royal Institute of Technology, at Stockholm, N. J., has a primary coil consisting of 125 feet of No. 8 wire. The secondary coil is over 20 miles in length, of No. 36 iron wire. The core is composed of a bundle of No. 26 iron wires, wrapped in oil silk and shellac. With these large dimensions coils, this coil has given sparks 21 inches in length, capable of piercing through solid glass three inches in thickness.

Specific Volume.

The lower that various metals have different weights that means, for the same size a piece of [illegible] weighs [illegible] ounces is about [illegible] ounces of metal has a different weight; in most lighter [illegible] weight of 100 cubic inches of the specific [illegible] ounces, and a cog of aluminium [illegible] the specific [illegible] of iron of the same size. The specific [illegible] of the same size in this water as mills; [illegible] Gravity of all metals, however, [illegible] [illegible] has been adopted that, in round numbers, [illegible] [illegible] 10 iron heavier; brass, [illegible] [illegible] 10 [illegible] heavier; [illegible] [illegible] 10 [illegible] heavier; [illegible] [illegible] 10 [illegible] heavier;

[illegible] Induction Coil.—If "A. R." has not yet constructed a coil giving say, 3in. or 4in. sparks, should strongly recommend him to do so, as he will find no difficulty in the method of winding and insulation, the one described by "Induction," in my estimation, is decidedly the best. Having made many coils on various plans, I can speak with knowledge of each. One just completed, giving over 6in. sparks, has the primary wire wound in four sections, as described on his plan. I have, since making the above, altered one I had previously made on Ferguson's plan to "Induction's," which is very considerably improved. The horizontal or old plan is perhaps the easiest to wind, but the other is the best when it is once made a success. Ferguson's is better still. The secondary wire being divided into two halves, the tension is necessarily half of some, leading to strike to leaves below. Still the outer layer of secondary wire is under great tension, as in the single coils. The middle line is also a source of danger should it get moved, as in the case of the one I have referred to, when the wire was broken, as it passes under or through the disc. In large coils of this description, I should prefer the middle line to be dead. The second paper (that of "Induction," which is well understood) offers advantages which none of the others possess. The absolute certainty of insulating every inch of wire, as "Induction" says, eliminates all danger and responsibility of breaking down insulation, and consequently of waste, the greatest care, possible, and certainly of economy, and, I believe, from 25 to 50 per cent. longer wand, should recommend it. If I had to make twenty coils instead of only the same plan, believing it to be in the end the most economical, I am certainly cheaper of all I have tried. The effects of the condenser in the case of "sets" construction, of dividing secondary into four, five, or six divisions or concentricals, I have not yet tried, but will say no more about it than that it is still determined to try a large coil I shall be glad to hear the experience of any practical researcher in electric theories, as I think there exists no more difficulty in construction of a coil to give 20in. or 30in. spark than one of 6in., except perhaps a very large increased size, &c. Too much cannot be said in favour of the Ruhmkorff coil, and some system may be resorted if an actual shock occur, which would not be the case when wire is varnished or insulated with such mixture, as recommended by some.—OBLIQ. C.H.

[illegible] Record 76

INCREASING THE SPARK OF THE INDUCTION-COIL.

To the Editor of the Scientific American:

Reading over the very interesting article of Prof. Houston in the Scientific American Supplement No. 41[illegible], 1876), I smile an experiment in which I put to a practical use the lengthening of the spark of the Ruhmkorff by connecting up of the poles of the secondary wire with a large surface, although it must be known to many of your readers, I have described it below as it is of interest just now in connection with the question of "electric force."

Desiring, during the winter of 1874, in a lecture on electricity at St. Francis Xavier's College, New York, where I have professor of physics at that time, to show the application of the inductive coil to lighting, I made the same arrangement with a dozen large Bunsen cells of the same pattern as those used at Niblo's Garden Theatre. The spark, however, would not pass when all were connected; but if only three or four were connected it passed quite readily between the platinum points and illuminated the gas. I had no difficulty in switching—as the coil was small, giving, as the most, a 1inch spark—the spark was too weak. On the following day, however, on repeating the trial, by accident one of the secondary wires leading to the burners came in contact with the iron work of the chandelier, and as the wire was uninsulated, communication was established with the gas-pipe. Immediately the spark, which previously had refused to pass between the platinum points of the burners, was so much strengthened that it lit the twelve burners without difficulty. I then connected one of the secondary wires permanently with the chandelier, and the spark never failed to pass even with less battery power. As you will readily see, this was nothing but another instance of Prof. Houston's discovery of increasing the spark of the induction-coil by connecting with a large surface, and is readily explained in the same way.

It may not be out of place to state in conclusion that both of your valuable journals, the Scientific American and the Supplement, are a real wonder to all the Belgians to whom I have shown them, being far superior to any similar journal on the Continent.

Samuel H. Pushee,

13. L'application du courant électrique pour l'extinction des incendies, par A. Tolhausen. (Telegraphic Journal, vol. III, page 285).

Un thermomètre forme par l'augmentation de la température le courant d'une pile qui met un électro-aimant en mouvement. Celui-ci ouvre le robinet d'un tuyau qui est en communication avec une chaudière à vapeur. La vapeur remplit tout tout l'appartement où l'incendie s'est déclaré et éteint le feu. De que cette application présente de nouveau est la combinaison de l'électro-aimant avec le robinet. Quant au principe de reconnaître à l'électricité pour signaler un incendie, il est depuis longtemps connu et employé sous différentes formes. Nous mentionnerons ici spécialement le système ingénieux de découvrir au moyen de l'électricité une fuite de gaz dont les conséquences, on le sait, peuvent être très-graves. L'on place dans l'appartement une capsule fermée par un couvercle de grès poreux. S'il y a fuite de gaz, la pression du gaz dans l'intérieur de cette capsule sera bientôt plus forte que celle d'une atmosphère, une colonne de mercure monte et ferme le circuit d'une pile et le signal d'alarme est donné par une sonnerie.

May 11, 1876] NATURE 27

through which the sun's heat is conveyed to and from the earth; the lower and denser strata absorb the greatest amount, and are necessarily the warmer;" a sentence of which a tenth could scarce atone every word. Again, "Gases, &c., which *rapidly* lose their own heat and *slowly* acquire that of others are susceptible of being copiously wafted." The italics are ours. And once more, "when the temperature of the air is reduced below that of the invisible vapour it contains, the moisture becomes visible." These sentences could be multiplied till we might wonder if it is really a book on *Physical* Geography we are reading. But these are serious defects, and we wish they could be altered. By the side of them it is of the merest importance that while we read in the Preface that "this every" yet on turning to the temperature of the sea, where the most important changes have taken place in our knowledge, we are still referred to Sir James Clarke Ross, and told that the present mean sea-temperature of the Antarctic temperature of 39°, for which at the equator we must descend deeper than anywhere else. We can scarcely imagine that any amount of clearness will atone for these things; let us hope they will be seen to before the edition in the ninth is required.

The Flora of South Australia. By R. Schomburgk, Ph.D., Director of the Botanic Gardens, Adelaide. (W. C. Cox, 1875.)

We have here a complete list of the indigenous flora of South Australia, both tropical and extra-tropical, with some general remarks prefixed. The most predominant natural orders in the colony are Leguminosæ, Myrtaceæ, Compositæ, Proteaceæ, Cruciferæ, Rubiaceæ, and Graminaceæ. The genera and species are remarkably circumscribed in area; many are found in one spot alone. The colony is singularly devoid of native edible fruits and roots; on the other hand it produces abundance of valuable timber-trees and of plants suitable for the manufacture of paper and other fibres, and for the production of dyes; but most of the valuable crops are naturalised plants, introduced from Europe or other parts of the world.

Theory of Electrical Induction

In NATURE, vol. xiii. pp. 457, 475, Prof. Paul Volpicelli gives an exposition of the two theories of electric induction, containing copious references to the writings of electricians, and numerous experiments of his own. It is remarkable, however, that he has not referred to any of the articles on the works of Poisson, Green, Thomson, Beer, Betti, &c., who have studied the mathematical theory of electric action, but he has not even introduced the subject into his exposition, unless we are to take the word action in the sense of potential, where he says that a certain portion of electricity possesses tension while another portion does not.

The result of this mode of treating the subject without calling in the aid of those ideas and phrases which the progress of science has developed, is to convey the impression that the whole theory of inductrical action consists in the surface of conductors and in very imperfect and vague conditions, whereas there is a part of electrical action in which we can trace more distinctly the correspondence, quantitative as well as qualitative, of the phenomena with the laws of electricity. It appears, however, from what M. Volpicelli says, that an erroneous theory of what it ought to be superseded by a more correct theory first proposed by Helmholtz.

Both theories admit that if an insulated conductor, without charge, is acted on by a charged inductor, the surface becomes electrified, oppositely to the charge of the inductor on the parts near the inductor, and similarly to the charge of the inductor over, and that both these electricities are produced with equal intensity. Across the second, that of Melloni, assumes that the "endowed with tension," while the other kind of electricity is entirely "latent or disdissimulated."

The only sense in which we can attach to the word "tension" or potential function, in the which modern writers mean by "potential," is often used in a vague manner, whereas potential is strictly defined.

Then a point is spoken to and to have a certain electric potential, and since all points of a conductor in electrical equilibrium have the same potential, we speak of the electric potential of the conductor, but we do not speak of the potential of a charge of electricity, or of electricity being endowed with potential.

Such language would only lead us into error.

Let us suppose the inductor to be charged positively and the insulated body to be insulated and charged without charging it, then, since its insulation prevents any electric communication with other bodies, its total electrification must remain zero, or there must be as much positive electrification as there is negative.

Hence for every flux of electric force which terminates on the surface of the insulated body and falls on the inductor, there must be a flux from the inductor to the body, there by either which passes from the inductor body and falls on the surface of the insulated body must therefore be equal to the sum. The between that of the inductor and that of the walls of the room, which is generally taken as zero. The potential of the insulated body is therefore positive.

There is no portion of the surface of the induced body a region nearer the inductor which is negatively electrified, and a region farther from the inductor which is positively electrified. These regions are divided by a neutral line on the surface, which is the surface of the section by an equipotential surface in space which has the same potential as the insulated body. The total charges on these two regions are exactly equal but of opposite signs.

If a small insulated conductor is placed in contact with any part of the surface and removed, it will be found to be electrified in the same way as the part of the surface with which it was in contact. A fine stout needle point, or a burning paraffin, placed on any part of the surface will dissipate the kind of electricity which exists on that part of the surface. See Riess, "Reibungs Elektricität," Art. 247.

If any part of the induced body is placed in electrical connection with the earth by touching it with a fine wire or by native electricity will be discharged, and the potential of the induced body will be reduced to zero. This will be the case whether the part touched be positively or negatively electrified. The quantity of electricity discharged will be the product of the potential of the induced body into its electric capacity.

After this discharge every part of the surface of the induced body will be negatively electrified, but the parts nearer the inductor more than those which are further from it.

In mathematical treatment of the subject Sir Thomson has found it convenient to divide the electrification into two parts, each distributed over the induced body according to its own law.

(*a*) The induced electrification when the induced body is connected to earth, and the charge of the inductor is zero. This is found to be negative on every part of the surface, but the density is greatest where it is nearest.

(*b*) The electrification when the induced body has a potential 1, and the inductor, still in the same place, has no charge. The electrification is positive on every part of the surface.

From a knowledge of these two distributions it is easy to determine a third, in which the total electrification is the algebraical sum of (*a*) and (*b*), and is such that the total electrification is zero.

We might then assert that the electrification (*b*) is free, because it will be discharged if the body is connected to earth, but that the electrification (*a*) is latent or disdissimulated, because it will not be discharged to earth.

The only danger of this mode of exposition is that it may suggest to a beginner the notion that electricity, like water and other substances, may exist in different physical states, in some of which it is more mobile than in others.

This idea of variation of quality once introduced into the

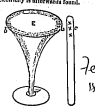
INDUCTION.

[13593.]—In Collin's work on "Electricity and Magnetism," by Fred. Guthrie, it is stated, at p. 111, that when an isolated conductor is suffering induction, the quantity of electricity by π, say, repelled over the surface, the end nearest to the inducer is accompanied by a quantity π of the opposite kind, and the inducer then with the earth, is found charged with quantity π of similar electricity whereas, if the other end be momentarily touched, no excess of positive electricity is afterwards found.

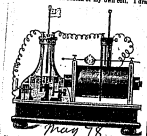


Let us now turn to p. 69 of Tyndall's "Lessons in Electricity," and see what he there tells us. Using his own words, he says:—"While the ball, A, is near the cap, inside the cask, B, with your finger touch the cask, and remove the inducer by touching it; you remove at the same time the positive electricity has disappeared. Has the negative disappeared also? No. Remove the glass tube, and as soon as you touch the cap at b by the inducer. It is charged negatively, and gives a spark with negative electricity. The mutual neutrality of the cap is first disappeared into negative electricity. By the contact between the inducer repelled by the cask and the fibres. The repelled electricity is free to escape, and the inducer and on your touching them with your finger; but the attracted electricity cannot escape as long as the inducer remains there. On removing the tube which divided the negative fluid in boulogne, that fluid immediately rushes to the whole cask, the whole cap." Now, according to Guthrie, the charge on the insulated body will depend on whether it is connected with the earth, and therefore it can no longer believe that the electricity collected on the end of the insulated inducer is as far as it goes to find collected on the most remote part of it; but Tyndall tells us that the electricity collected on the end of the insulated inducer cannot pass off until the earthing rod is removed, and hence that my brother-inductors may favour me with their opinion as to its above.

Newton, 2, O'Connor Terrace.

New Dielectric Constant. Be M. Neyreneuf.—On examining the comparison of different insulating substances employed as the dielectric plates of a condenser, the author has established that for glasses of the same nature that the ratio $\frac{e}{a}$ of the thickness e to the number a of sparks corresponding to a given quantity of electricity was constant. He has, almost determined the value of this ratio for the varieties of glass met with in commerce. For substances much more insulating—such as ebonite, caoutchouc, and paraffin—the above ratio, which may be called the condensing constant, goes on increasing in a marked manner with the thickness. Consequently, only results obtained with plates differing respectively little in thickness are comparable.—*Compt. Rend.*

[13594.]—Induction Coil.—As this query seems to call directly on its way in the U.Q. column, I am suggesting a query addressed to correspondents, so send the inclosed sketch of my own coil. I drew

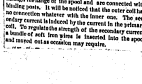


May 78

it as it stands on the table before me ready for action. The primary coil is No. 1 wire, the secondary one No. 36, diameter. The cells I use are three Nos. 20 secondary, with salt and water. In fact nothing. I just give the hands of the current, and the length between the terminals. The secondary is 1 inch long, between the terminals. The secondary is several millimetres, but I have filled up the space with a thin electric tube. I think I have described it. Will some correspondent please say whether I have arranged paper and an adequate amount of tinfoil. I have no means of testing.

J. P.—I have no means of testing my coil, however, so don't know to what extent it is reliable. However, send this in hope it may be useful.—Cuthbertson.

(10) F. P. C., W. A., and others: An ordinary induction coil may be made in the following manner: Turn a spool, A, of wood or hard rubber, 4 inches long with flanges, about 2½ inches in diameter. The spool should be ¾ inch internal diameter and quite thin. Upon this spool wind two layers of No. 18 insulated copper wire, as shown at B. Then around the coil thus formed two or three thicknesses of paper which has been soaked in melted paraffin. Upon the paraffin paper wind from 300 to 400 feet of No. 40 silk insulated copper wire, placing under each layer a thick piece of paraffin paper. The ends of the wire of the inner or primary coil extend outward through the flange of the spool, and one of them is connected with a post, B, to which is also attached a screw binding spring, supporting an armature in front of a short soft iron plug in the end of the spool. The current breaking spring has the form

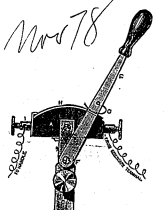


attached in it a small disc of platinum, which rests against the adjusting screw in the post, B. This post is connected with the battery, P, and the latter connects also with the terminal of the primary coil. The ends of the wires of the outer or secondary coil extend through the flange of the spool and are connected with binding posts. It will be noticed that the outer coil has no connection whatever with the inner one. The secondary current is induced by the current in the primary coil. To regulate the strength of the secondary current a bundle of soft iron plugs is inserted into the spool and moved out as occasion may require.

REGULATOR FOR INDUCTION COIL.

By J. E. Floyd.

A A is a block of ebony, of the shape shown, and about ¾ an inch thick. It is supported by means of the pillar, B, which fits into a socket, C, secured to the base board of the coil. This socket is situate between the secondary terminals, and is also used to support a small ebonite table for spark experiments, etc. The screw, D, secures either attachment at pleasure. The lever, E, turns on a screw at F, and carries a spring, G, which presses on a strip of soft leather, H, glued over the top of the block. The leather is well impregnated with plumbago, and a small portion of electrical amalgam is rubbed into the surface. The binding screw, I, is in connection with the leather at one end, while the other is connected with the lever support by means of a wire through the



Mar 78

July 5, 78

block. The instrument is placed in the secondary circuit, as indicated in the sketch.

When the lever is in the position shown, the current has to pass through the resistance of the impaired leather—the block is therefore reduced; but when it is turned over on to the other side, so that the spring is in contact with the brass at F, the full benefit of the coil is felt. The best proportion of amalgam can be determined by experiment. This regulator is much better adapted than the water regulator for singular other parts of the coil.—*English Mechanic.*

Effect of Induction Currents on the Spinal Cord.—Dr. William Miller Ord, Physician to St. Thomas's Hospital, has been investigating the effects of Faraday's induction currents on the spinal cord of dogs. The dogs were killed by chloroform; and the cords being quickly exposed, were subjected to the currents for different periods and in different directions. Dr. Ord observed that the cord broadened under these, through which the currents passed longitudinally, and narrowed when transverse currents were applied. The following are the conclusions as communicated to the Royal Society:—1. That, in young dogs, the protoplasmic constituent of the gray matter contracts *ex vacuo* under the influence of strong faradaic currents. 2. That it expands unequally and irregularly by reason of its unequal and limited sectional area, causing thereby condensations at certain points—notably in the anterior horns and around the central canal—and rarefaction at others—notably in the middle of each crescent; such rarefaction going sometimes to rupture of tissues. 3. That nerve-vesicles contract in various degrees according to the strength and duration of current, and that while they tend to contraction to become spherical they also tend to become uncoulated. 4. That the vessels are in some places strongly constricted and empty; in others dilated and filled with blood clot, with the appearances of oedema. 5. That the appearances correspond so decidedly with the conclusions in cases and seizures to give ground for the supposition that contractions, such as are produced by electricity, do actually occur during life under the effect of nervous shock, and may be phenomena causal or associate of disease.

The Voss Induction Machine.

[13595.]—I was much interested in the article of "W. W.," which appeared in your last issue, as this difficulty so nearly resembles my own. Two or three of the earliest my practice in the query column of this paper. I am myself still a novice in the subject of electricity, and when I saw the description and illustration, I felt that I could understand it in the reply of "H. S. A." I was very obliging, I immediately set about making one, and it is now at work. I have used Mr. Sutton's "Electrical Manipulation" as my guide. The condition I made has a moving plate of vulcanite, which is glass by the coating of shellac, the varnished glass. I have modified the form of the sectors, the tinfoil being adhered to the parts which would influence the principle. My machine starts without priming; but to do this, the sectors to be revolved a few seconds smartly. The velocity is from 15 to 20 revolutions per second.

At its inception, certainly influenced by the state of the weather, as on some occasions it will take a force to set it till slightly covered. I find that the heat of the hand held behind the stationary plate for a few seconds will start it readily. The disturbance of temperature gives the initial charge.

I have not yet tried the effect of the form "G. A. A.," though the pencil is not exactly shown in the sectors. They are 10 in number, and from the description. They are to be placed 60° from the vertical or 30° from the horizontal centre. The direction of revolution is not given by "G. A. A.;" this should be from the brushes to the collecting combs, and not up to the right in the machine. Has this been attended to this? The use of the vertical comb is to increase the electricity, or does it act as a guard to the — electricity to convince when the discharging terminals are formed strikes at distance, and this arrangement prevents the over-strain? Although I have not yet tried the form "G. A. A." a difficulty I have many Holtz machines, and it is also from the experience of many of course that the brushes need not touch the — commencing to work. Some years ago I made Holtz machine of the form represented at page 241 of Bartlemann's "Electricity"—viz., with two plates and four opposing directions; but I brought the sectors to each other and added another pole, which took from each alternately the part of the sector which it could use. This machine acted admirably, but, of course, had to be glassed. I have been staying my question to prevent the cause of my failure; but have yet only had time to look at the principle of the action of the machine. I would be glad to view my other information I can on "S. W. W." if he will communicate with me.

A. B. Molison.

HOW TO MAKE AN INDUCTION COIL.

By Gen. M. Hoxsie.

Faraday discovered in 1832 that a galvanic current was capable of inducing other currents in wires near but not in contact with the conductor of the primary galvanic current; those he named *currents of induction*, or *induced currents*.

Since the discovery of Faraday, the phenomena of induction have been exhibited by many forms of apparatus; but the most striking example of inductive action is afforded by the induction coil. Prominent among makers of this instrument are Ritchie, Buhmkorff, and Ladd. The performance of the induction coil is familiar to many of the readers of this journal; but its construction is not so well understood.

There are two methods of making an induction coil; the simpler, cheaper, and perhaps the best will be described in connection with the accompanying engravings, which, with the exception of figure 4, are exactly one half size, and may be used as working drawings from which to construct the instrument. Figure 1 is a plan view. Figure 2 is a central, vertical longitudinal section. Figure 3 is a vertical transverse section, taken through A, B, and C. A, A, wood base, B, B, wood ends, and C, C, wood sides, supporting the condenser. Figure 4 represents the under side of the base, in plan, and the condenser, in perspective, and shows the connections.

The coil consists of two portions, the inner or primary, and the outer or secondary. The primary coil, D, consists of two layers of No. 16 cotton covered copper wire, which are wound upon a spool composed of the thin brass ends, D, D, and the wooden tube, A, and the handle, HH, which are of vulcanite, or hard vulcanized hard wood. The tube is $\frac{3}{4}$ inch internal diameter, and the heads have each a central hole of the same size. The holes are enlarged or countersunk to receive the ends of the tube, A, which are glued or cemented therein. In the head, D, there are two small holes near the tube's central hole, for the terminals, *e d*, of the primary coil. One of these terminals is put through the head before the winding operation is begun; the other, after the winding is finished.

The primary coil must now receive four coats of moderately thick alcoholic shellac varnish; each coat being allowed to become dry before another is applied. When the primary coil has become thoroughly dry and hard, it is covered with three or four layers, D, of stout cartridge paper, which is fastened by a little gum along its outer edge. This paper is covering must fit between the heads, HH, perfectly, and must be well smoothed and rounded, and varnished with shellac, taking care to cover the joints at the ends, and also to varnish the inner face of the heads. The secondary coil, E, is wound in two sections separated by an insulating medium, G, which is applied in the manner presently to be described. The coil, E, is of No. 36 naked copper wire; the two sections being connected at H.

The winding is best done in an engine lathe, the wire being allowed to pass through a fine girdle in the tool post, and the lathe being set as for cutting a fine screw. The coil, E, should be about three quarters of an inch in depth, and its width must be the same as that of the primary coil.

The different convolutions of the wire should be as near together as possible without touching. To accomplish the same thing in an ordinary foot lathe, a piece of quite thin brass should be bent together in a U form, and the wire should be allowed to pass between the two sides thus formed; the thickness of the metal will regulate the space between the adjacent coils of wire. The winding begins at the middle, leaving the terminal, H. When one of the heads is reached, the coil or layer, formed in the manner described, is covered with three thicknesses of common white tea paper or quite thin writing paper, the edge of which is fastened with a little gum. The winding of the fine wire is now continued toward the center of the coil; when the second layer is complete, it is covered as in the case of the first coil, when the third is wound on, and so on until it is about $\frac{3}{16}$ inches in diameter. The secondary wire should not be wound close to the head, a space of about $\frac{1}{4}$ inch should be left. After winding one of the sections of the secondary coil, the other may be proceeded with after changing the coil with the spool in the lathe, so that one section may be wound as a continuation of the other. The inner terminals are connected at H, and soldered; the outer terminals are connected with the binding posts, F, which are screwed into the upper edges of the heads, BB'. For the sake of strength the ends of the secondary wire may be four or six times larger than that of the coil. The outer layers of fine wire are separated from the primary coil by several thicknesses of tea paper, which is while enough to reach from the head to about two-thirds of the coil section; the whole is then covered by a wrapper of stout paper, having a hole directly in the middle of the top, through which is poured melted resin in which has been added a very small quantity of beeswax.

This forms the insulating medium, G, which prevents the spark from leaping from one section of the coil to the other. After the resin cools, the thick paper is removed and a covering of smooth heavy paper is neatly put around the coil, and upon it is wound as closely and as neatly as possible common smooth fastened thick thread. This latter is not essential, of course, but it gives the coil an excellent appearance and forms a really good covering.

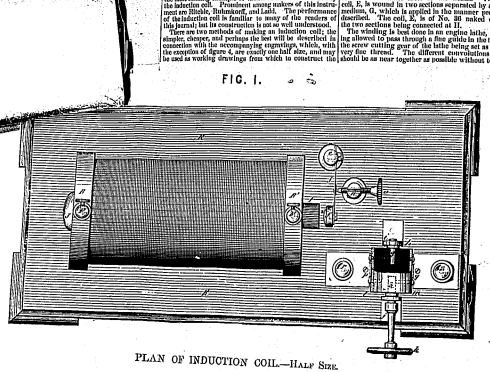

FIG. 1.

PLAN OF INDUCTION COIL.—Half Size.

This color is printed upon cloth prepared with a fatty acid, an essential condition of success. About one part of salicylic acid should be used with 20 to 30 parts of water.

Steam one and a half to two hours. Wash and soap 20 minutes at 122° F. Take through boiling lime water 15 grains of quicklime per 20 fluid ounces of water. This gives a greenish blue shade, owing to the formation of a lime soap.

Wash well and soap at a boil, which restores the blue to its original purity.

Barium and zinc salts produce upon blue alizarine an effect similar to that of alum. Dilute soda and potash turn the violet shade to a decided blue. Certain oxides almost insoluble, such as magnesia and oxide of zinc, act in a permanent manner upon alizarine blue when already fixed so as to modify its tone.

The alizarine blue fixed by our process bears chloride of lime and light. It turns certainly more gray on exposure to the sun, but its fastness is considerable; so that of a vat blue.—*Bulletin de la Société Industrielle de Mulhouse.*

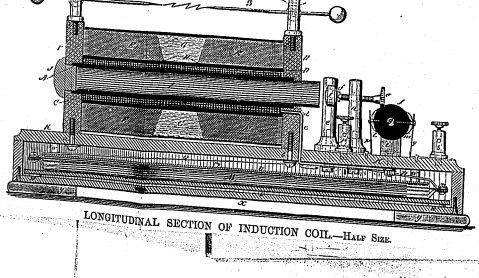

FIG. 2.

LONGITUDINAL SECTION OF INDUCTION COIL.—Half Size.

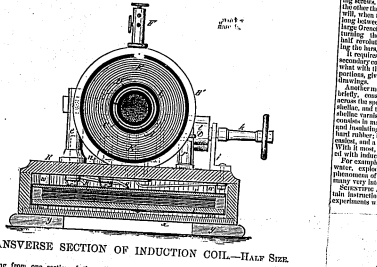

FIG. 3.

TRANSVERSE SECTION OF INDUCTION COIL.—Half Size.

In the base of the instrument is placed the condenser, M, which is composed of sheets of thin tin foil alternating in position as shown in Fig. 4. The ends of the sheets, O, project beyond the sheets, P, to the right, the ends of the sheets, P, projecting beyond the sheets, O, to the left. The sheets, O, are insulated from the sheets, P, by sheets of paper, N, which have been coated with white vulcanite varnish and well-dried. All connected together at one end, and are electrical connected with the wire, B. Similarly the sheets, O, are connected with the wire, H.

A piece of pasteboard, *r*, is placed upon each side of the condenser thus formed, and the whole is fastened together with tape running around it in two directions, and the condenser is held in place by bits of cork, *s*, which are pressed by the bottom, N, when it is in its place. The condenser has 40 square feet of tin foil surface.

The battery wires are connected with the binding posts, *r r*, the former passes through the springs, *g g*, bars, *f f*, pivots, *h h*, to the posts, *i j*. The post, *j*, is connected directly with the terminal, *c*, of the primary coil. The post, *i*, is connected by the wire, *k*, with the post, *n*, and the terminal, *d*, of the primary coil, is connected with the post. The battery current passing through the primary coil renders the wire bundle, *l*, magnetic; the hammer, *f*, attracted toward it, breaking the electrical connection at the end of the screw, *s*, when the iron wire bundle loses its magnetism, and the hammer flies back until the spring, *f*, again touches the screw. When the current is broken at the end of the screw, *s*, the secondary current is discharged from the primary coil; but when the primary current is discharged by the wire, B, with the condenser, *e e*, the spark is very much increased in intensity, as the extra current is diffused in the condenser, and the strength of the secondary current is very much increased.

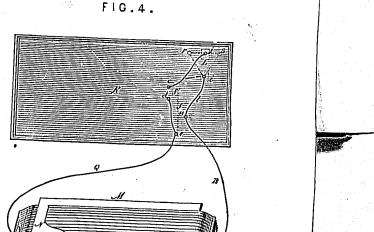

FIG. 4.

DIAGRAM OF CONNECTIONS, INDUCTION COIL.

The engravings. The coil is secured to the top of the box, *a*, a little nearer one end than the other, by two screws, *a b*, which pass upward into the heads, BB'. Near the head, B', there is a brass standard, *c*, to which is secured one end of the spring, *f*, that supports the hammer, *f*, exactly opposite the center of the wire head, I, and about $\frac{1}{16}$ inch distant from it. Opposite the middle of the spring, *f*, and $\frac{1}{16}$ inch from it, there is a post, *g*, through which passes the platinum pointed screw, *s*, which touches a small plate, *f*, attached to the center of the spring, *f*. The post, *s*, is split longitudinally, and clamps the screw, *s*, with

some little pressure to prevent it from jarring loose by the vibrations of the spring, *f*.

The commutator, L, consists of a vulcanite cylinder on the bar, *l*, coming in contact with the pivot, *k*, and one of the screws of the bar, *m*, coming into contact with the pivot, *h*, and one pivot, *h*. The pivots, *k h*, are kept in posts, *j j*, which spring against the shoulders of the pivots to insure a perfect contact. The pivot, *h*, is elongated and provided with a wire thumb handle, *h*. The binding posts, *r r*, are connected by copper springs, *p q*, with the copper bars on the vulcanite cylinder.

Concluded from Supplement, No. 159.

briefly, consists in winding with covered wire entirely across the spool, and insulating each layer by a coating of shellac varnish or melted paraffin. Or another method consists in making the secondary coil of very thin sections, and insulating the sections one from the other by disks of hard rubber; but the plan here given is said entirely the best, and a coil made in this manner gives good results. With a coil of not all, of the experiments usually performed with induction coils may be accomplished.

For example, a small charge a Leyden battery, decomposes water, explodes detonating cartridges, light gas, exhibits the phenomena of electric light in vacuo, and may be used in many very interesting experiments.

Scientific American Supplement, No. 106, will contain instructions for performing a number of interesting experiments with the induction coil.

INDUCTION ON AIR-TELEGRAPH LINES.

Every well-versed electrician knows that when two neighbouring telegraph wires are working, the signal currents in one induce feebler but corresponding currents in the other. The effect of these induced currents on a very sensitive receiving instrument, such as the speaking telephone, is, to certain extent, causing a confused chemour of sounds which quite smothers up the small voice of that instrument. Now the tendency in telegraphy is, of course, to obtain greater speed of working on lines, and in order to do this more sensitive instruments are required. For the retarding effect also of earth induction on current signals, which causes them, as it were, to plough their way up against an influence tending to hold them back, and the wave-like form which the signals assume under this influence, render it necessary to make the receiving instruments more sensitive so as to appreciate smaller fluctuations of current strength, if greater speed be aimed at. It is evident, however, that there must be a limit to this sensitising of the receiver if the induction of neighbouring currents is to be left uncorrected, for the receiver may be made so sensitive that, like the telephone, it will be perturbed in its action by these induction currents. There is no mechanical obstacle to making receiving instruments which will record 1000 words per minute, could these induced currents be prevented from influencing them. Until the researches which Professor Hughes brought before the Society of Telegraph Engineers last Wednesday (March 12), very little, if anything, had been done by electricians to neutralise the evil. It has hitherto been evaded by them in employing powerful currents to work insensitive instruments, and in having recourse to multiple methods of telegraphy. The time is come, however, in which this question will have to be seriously grappled with by telegraph administrations, and as the sensitive telephone has been the means of bringing back the wandering attention of electricians to the subject, so has it been, in the hands of Professor Hughes, the means of enabling him to give us the first contribution towards a solution of the difficulty.

FIG. 1.

One of the cures for current induction suggested by Professor Hughes can be explained by help of fig. 1, where a and b are two neighbouring telegraph lines, one being longer than the other for the sake of generalising the case. Between each line and its receiving instrument a, a coil of wire a for line a, and b for line b, is inserted. Now the length of the wire in coil a is proportioned to the length of the wire in line a in the same ratio as the length of wire in the coil b is proportioned to the wire in line b, supposing the kinds of wire for each to be similar. The coils themselves are of the same diameter, only a will have more turns than b, the line a being longer than b. The distance d, between these two coils, also bears a relation to the distance between the lines, a relation found by experiment; and if the line a is directly above b the coil a should be supported directly above b and parallel with it. On the other hand, if a be not in a vertical line above b on the telegraph posts but displaced sideways, as on the French lines, then the coil a must be displaced laterally to a proportionate extent, while being above b. The coils a and b then posed form a compensating arrangement to the mutual induction of the two lines. This induction compensator, as Professor Hughes calls it, can be easily made by causing the coils to slide up and down a vertical stem in the case of wires vertically over each other, and giving them also a lateral motion in the case of wires placed otherwise. It is in fact an artificial bad line, just as Muirhead's inductive resistances are an artificial cable.

We have yet to see how it operates in neutralising the induction. Let us suppose that a signal current is passing in the direction of the arrow, along the line a and the coil a, to earth through the receiver R. Now if the coil a be wound in the same direction as the coil A, this current will evoke an induction current in the reverse direction in the line b and the coil b, as shown by the arrows. This induction current will make a false signal on R if it is, like the telephone, sufficiently sensitive. If, however, the position of the coil a be reversed with respect to b so that the current circulates round its turns in an opposite direction to what it did in the case we have just considered, the induction of the coil a on b will be such that an induction current will be set up in b in the same direction to the primary current through a, as shown by the arrow F. At the same time the induction current in a will remain, as before, in an opposite direction to the primary current in a. But the coils a, b have been so proportioned and placed with respect to the lines a, b, that the inductive effects in them are equal to those in the lines themselves. Hence the equal but contrary induction currents in a and in coil b neutralise each other and no false signal can be made on the receiving instrument a in circuit with a. In this way the two lines are screened from each other's dynamic induction. The adjustment of the compensating coils is best effected by means of a telephone in circuit, and Prof. Hughes employs a microphone placed near a ticking clock to give the sonorous currents. The adjustment is made by shifting the coils with respect to each other till no induction sound is heard on the telephone. The insertion of soft iron rods into the hollow of the coils also affects the balance very sensibly; and Professor Hughes finds that according as one or more of these rods are inserted the mutual induction of the coils is more and more lengthened out. By these rods the arrangement can be made to compensate for the length of the induced signal as well as for its intensity.

The plan of using a return wire for telephone circuits in order to overcome the induction clamour is a well-known one; but of working the wire in a disdiacting envelope in connection with earth, though efficacious in the case of ordinary electricity, is worthless for dynamic electricity. It occurred to Professor Hughes that the going and returning wire should be twisted round each other; but as was pointed out in a note of our last issue, this plan has been already patented by Professor Bell, and also by Mr. David Brooks, the American electrician. The

FIG. 2.

modification of this plan, shewn in fig. 2, is, however, due to Professor Hughes. Here A and B are the going and returning wires twisted round each other. The battery is earthed in the middle and the poles are connected to a double pointed reversing key K, so that when the key is worked by the sender, the signal consists of simultaneously applying the positive and negative poles to the two wires A and B. The receiving instrument is wound differentially, and the signal currents flowing along A and B in the direction of the outer arrows, work the receiver conjointly. The effect of the equal and contrary induction currents produced by primary currents in a neighbouring circuit, being in the same direction in both wires, as shewn by the inner arrows, pass in opposite directions through the receiver and are neutralise each other.

[illegible] JONES'S INDUCTION BALANCE. 77

[illegible] reading resembles into the [illegible] induction, especially as [illegible] has been lately made [illegible] important discoveries [illegible] Society of Telegraph [illegible] with an instrument to which [illegible] Induction Balance has been [illegible] known words, several of [illegible] by Prof. Hughes.

[illegible] consist of 100yds. of [illegible] each, and [illegible] are placed at a distance of 10 centimetres from [illegible] coils, and between them, at the distance of five centimetres, is a single coil. We have here two long lines and one intermediate short one. The induction of these coils on each other ensures the reduction on similar long circuit; the effects, however, are much [illegible] with coils them on straight wires, and [illegible] allows us to reproduce with a hundred [illegible] of a battery the full amount of inducting [illegible] on a line a hundred miles or more. The [illegible] of having a neutralising coil on a line [illegible] that it represents, as we have found, the most difficult portion of the problem. The [illegible] for the induction on these lines, we have three small No. 32 copper (covered) coils; three of these [illegible] together so as to form a compact bundle are gradually approached until the exact balance for each line is found; and this is found very rapidly, for we have only to slide it until [illegible] silence is obtained in the induced currents passing other wires. Those coils have a large or unequal lengths, the coils should be in ratio to the length of the line, say 100 yards of coil to 100 miles of line; but, from the practical effects obtained with the coils experimented with, Professor Hughes believes that 100 metres per 500 miles of line would be amply sufficient.

Each coil should be reversed by the key of the instrument at the instant of putting on the battery, and with these the compensation is most perfect, and lines that were full of powerful induced currents all become perfectly free from it; whilst it is no way millimites against the transmission of the battery current on its own line.

The invention is not only regarded as a great advance in telegraphy, for by its means the telegraph engineer will be enabled to meet electrical induction with its own weapons, and remove the cost of working his lines on expensive and troublesome items.

of a wire of pure copper, 1 knot (6,087 feet) long, and weighing 1lb. avoirdupois. (7,000 grs.)}

A. R_t at 32° Fahr., $= \frac{P}{W \times 4\cdot6} = 1089{\cdot}38$ ohms.

R_t at 75° „ $= 1089{\cdot}38 \times [1 + (\cdot00215 \times \frac{75-32}{1})] = 1100$ ohms.

Q. 6. How would you arrange twelve cells, each having an internal resistance of 4 ohms, so as to obtain the maximum current through an external resistance of 12 ohms.

A. Since the external resistance equals 12 ohms, and we require to make the battery resistance equal to this, if we put two rows of 6 cells each, and join them up in multiple arc, we shall have the internal resistance halved, because we have half the number of cells, and then halved again, because each cell is (virtually) twice the size. Therefore, $\frac{48}{4} = 12$, which is the external resistance exactly.

Q. 7. Demonstrate, by means of a diagram, the theory of the tangent galvanometer.—*(Not answered.)*

Q. 8. What work will be done in one hour by the current of five Daniells circuited through a total resistance of 100 ohms?—*(Not answered.)*

Q. 9. A mirror galvanometer, in circuit with a Latimer Clark standard cell (*E* = 1·457) and a resistance of 3,800 ohms, gives a deflection of 120 divisions of the scale. Through what resistance would the E.M.F. of one volt give a deflection of one division?—*(Not answered.)*

Q. 10. Required the constant for microvolter current, with values in last problem.

$$A.\ \phi = \frac{D\,H}{2\,G} = \frac{100 \times 3800}{2 \times 1\cdot457} = 131.$$

Q. 11. A reflecting galvanometer, placed with its mirror at a distance of 36 ins. from the scale, is shunted with a shunt of mult. power 100, and is then circuited with a single Daniell cell through a resistance of 8,000 ohms. Under these conditions it gives a deflection of 3·25 *inches* on the scale. What is the *figure of merit* of the instrument, or the resistance through which one Daniell cell will deflect the *needle* through 1° of arc?

A. In this case $\phi = 2{\cdot}6$, and since (by)

$$R_1 = \frac{\phi \times 31{,}607{,}000}{I} = \frac{2{\cdot}6 \times 31{,}607{,}000}{32} = 2{,}287{,}861.$$

(The correct answer would be 2,049,161 ohms.)

Q. 12. A galvanometer having a resistance of 180 ohms is placed in a telegraphic circuit of high resistance, and is then traversed by a current of 200 microvolters. The instrument is afterwards shunted with a shunt of resistance 20 ohms. What will now be the current traversing the galvanometer?

A. The mult. power of the shunt is $n = \frac{200}{20} = 10$. Therefore, the current in the galvanometer equals $\frac{200}{10} = 20$.

(No note book used.)

ELECTRICAL INDUCTION.

EXPERIMENTAL RESEARCHES [INTO MEANS OF PREVENTING INDUCTION UPON LATERAL WIRES.*

BY PROF. D. E. HUGHES.

The induction upon lateral wires has of late years been a serious question upon telegraph lines—the constantly increasing number of wires upon the same poles, added to the adoption of high speed and consequent sensitive apparatus, renders the study of these effects of the first importance.

The disturbing effects have become each year more and more remarked, and in 1868, by the desire of the French Telegraph Administration, I undertook a series of practical experiments with the view of finding a remedy. I soon perceived that we had to deal with a question of a more complicated nature than was at first supposed. We found, then, that we had to deal with the static charge of the own line and the dynamic induction of the lateral wires; that the effects of each were very different; and whilst it was easy to deal with the comparative feeble static charge, the more powerful and rapid effects of dynamic induction could hardly be suppressed. By introducing extra resistance coils we could reduce the induced current, but at the same time we should reduce the current with which the line was working. The remedy was in most cases (particularly during faulty insulation) worse than the disease. Condensers and polarisation batteries would allow the momentary ind currents to act, whilst they prevented the more prolo currents of the distant stations. The only remedy we then k was by the introduction of an electro-magnet, with an arma fixed upon its poles—thus being a closed magnetic conduc This practically absorbed or destroyed all the short moment currents; but then if on this line the apparatus was worked high speed, with consequent short currents, we practically ca the best part of the current needful.

In this case, whilst the remedy was practically perfect, t apparatus at low speed with comparative long currents, fa useless for those working at high speed requiring shorter curre and, consequently, more sensitive organs of response.

Other duties prevented me at that date from following up t line of research. The disturbances on the lines from this ca have been on a constant increase from the adoption of ra rapid, and consequently more sensitive, organs; and, in t *telephone*, we have at last arrived at an organ of rapidity a sensitiveness which reveals the constant induction which a s main reason why the telephone has not been more largely adop upon telegraph lines.

In a late paper upon *inductor* we brought to notice t powerful organs of research in this field that we possess in t telephone and microphone; and we thought that by the aid these we might investigate, theoretically, the cause and remed for lateral voltaic induction.

The following experiments are a *résumé* of the results t gained :—

We made use of three separate and distinct means of resear The first consisted of two or more parallel wires, 25ft. long; one being used as a primary was connected to battery and tele phone, with clock as source of sound (both ends of wire being earth). The secondary wire, upon which the induced cur was observed, was connected to telephone—both ends of t line also being to earth.

The second arrangement was made in order to study effects upon a much shorter length, and with more accuracy tha could easily be obtained on the longer line.

Two parallel—1 millimetre—copper wires were strung upon board, 15in. by 12in.; these wires were placed 16in. apart, both united at one end with one Daniell element, placed near The free ends of these wires could be put alternately in connection with battery; and thus, if we surrounded one of these wi with tinfoil, or other means of protecting wires, we could ascer the degree of protection obtained, by comparing it with the unprotected wire. A difficulty was at once felt in obtaining sufficient induction upon a parallel wire of such a short length. We obviated this, however, by the construction of a flat rectangular coil 100 turns, having 6in. side exterior. Now, by placing either of the sides of this coil near primary wire, we had 100 parallel induced wires, of a few inches—the influence, therefore, was multiplied greatly; we had also in this coil, on the opposite side, 100 parallel layers running in a contrary direction, so the resultant strength of current was simply that due to the different distances; and it was a rule to diminish this, as far as practicable, that we made the coil square. The sound obtained by this means was amply sufficient for all the researches needed.

The third means was that usually employed, namely, the use of coils either superposed or wound together in the same helix by this means powerful effects could be easily obtained; and as the results were identical and verified by the three systems, we will not relate the experiments with coils.

I. If we construct two flat coils of 100 yards of No. 36 copper wire each, and join one as primary to battery and microphone, the second coil as secondary, joined to telephone alone, we find that by placing one of these coils near, or within a few inches, distance from the other, we hear distinctly the sounds of the clock on the microphone. Our object now being to screen the secondary coil, so as to reduce the induced current, and consequently sound obtained on telephone, we joined both coils to the same earth plate, without effect. We then took a sheet of copper, one millimetre thick, 12in. square, and placed it between the coils, without effect; joined both coils to this plate, as if it were an earth plate between the coils, but no perceptible reduction of the induced current was thus obtained. We then put 10 thicknesses of iron plates, 12in. square, between the coils, again joining them as earth, but still no perceptible reduction.

II. The two coils were surrounded with several layers of tinfoil, thus enclosing each separately in a continuous metallic sheath. This, however had no effect, and sounds were quite as loud, even when the sheaths were joined to earth. Placing both these metallic covered coils in a vase of salt water, and all to earth, had not the slightest effect, even when the copper plate was also interposed between the coils. Theoretically, these ex-

* Paper read before the Society of Telegraph Engineers.

† "Comptes Rendus de l'Académie des Sciences," Paris, December 2, 1878, and January 20, 1879.

wire. If we can send into the wires B and C an opposing current of exactly equal strength and duration to that of the induced current, we evidently reduce the induced current to zero, and have consequently no disturbing effects on those wires.

After numerous experiments, I have found that if coils of wire be so placed in relation to each other, that their relative distance represents the relative distance of the wires from each other, and if each line at its transmitting station be joined to earth through these coils, then in passing the battery current through one of these coils to its line, it would induce a current whose direction would be contrary to itself; and as this would be exactly what takes place on the line itself, we should (supposing the coils to have equal inductive force to the lines) simply double the induced current, and the disturbing effects would be twice as much as what they were before the use of the coils; but if at the same instant that we send battery on line we reverse the terminals of the coil in relation with it, then the induced current sent by coil will be in the same direction as battery on primary, and this would neutralise the contrary direction of the induced current, reducing it to an absolute zero.

I have embodied this idea in the instrument which I present this evening, consisting of a series of coils of insulated iron wire. There are two of such coils, 10 centimetres diameter, 100 metres long, connected together so as to form a single line; these are placed at a distance of 10 centimetres from two similar coils, and between them, at the distance of five centimetres, is a single coil. We have these two long lines and one intermediate short one. The induction of these coils on each other represents the induction on similar iron aerial wires; the effects, however, are much greater with coils than on straight wires, and this fact allows us to reproduce with a hundred metres of wire only the full amount of induction of a line of hundred miles or more. The reason of having a shorter intermediary coil is, that it represents, as we have found, the most difficult of the problem.

To compensate for the induction on these lines, we have three small No. 22 copper (covered) coils; these are so arranged on a graduating scale that they can be gradually approached until the exact balance for each line is found; and this is found very rapidly, for we have only to slide it until complete silence is obtained from the induced currents passing other wires. These coils have no necessary absolute relation as to length or power to that of line, as we can increase the force by approaching them; but in the case of intermediary wires, and also several wires of same or unequal length, the coils should bear a definite ratio to the length of the line, say 100 metres of copper coil to 100 miles of line; but, from the powerful effects I obtain with the coils I have experimented with, I believe that 100 metres per 200 miles of line would be amply sufficient.

Each coil should be reversed by the key of the instrument at the instant of putting on the battery, and with these conditions the compensation is most perfect, and lines that were full of powerful induced currents all become perfectly free from it, whilst it in no way militates against the transmission of the battery current on its own line. But as our object this evening is not to bring forward new instruments but to discuss the question generally, we will at once sum up our conclusions.

There are three points on ordinary telegraph line or lines where we may attempt a solution of the difficulty by compensation or other neutralising effects, namely—receiving, intermediate, and transmitting stations.

At the receiving station, ordinary induction coils, or the compensating coils I have described, would be injurious, as they would not be reversed in relation to each other, and would thus increase the induction.

Voltaic currents, direct or by derivations from primary line, would answer only where the signal consisted of a dot or a short signal exactly equal in duration and force to that of the induced current.

Polarisation batteries, direct on line, would allow the induced current to pass, and if used as a derivation would require a very great resistance, and would allow the extra current from the working electro-magnet to affect all the coil.

Condensers would be similar to the polarisation or secondary batteries. Resistance coils would reduce the induction, but also in equal proportion reduce the voltaic current needed. Magnetic condensers would absorb the induction, but also absorb the first part or the part most needed of the voltaic current.

At the intermediate station all these would give contrary effects to those desired, except secondary batteries and condensers in derivation; but these would weaken the primary current, and for a line of ten wires would, from a calculation we have made, require 45 such condensers, and even then it would be impossible to fulfil all the necessary requirements.

At the transmitting station ordinary induction coils could not be used except for a line of two wires only.

Derivations from sending battery would require that a great resistance between line and earth should be introduced, and, moreover, the current would be prolonged beyond the induced current.

Polarisation batteries and condensers would also, if in derivation, require great earth resistance, and would require for a 10 wire line the same number of condensers as the intermediate station with like results.

Compensating coils, on arranged in the instrument we have submitted, fully meet the difficulty, giving perfect compensation for any number of wires, with but one coil to each wire, provided that the lines are used for transmission in one direction only for stated periods, and that they are arranged as in France, as already explained.

The perfect line, however, itself quite free from induction, and not inducing on other wires, and therefore requiring no compensating arrangement, is the double wire we have already mentioned, where both ends are to earth, and its electro-magnets wound differentially.

I have studied this subject with much interest because I believe that the future improvement in telegraphy depends in a great measure on its entire solution, and I hope that by a discussion on this subject new facts may be brought to light.

COMPANHIA TELEGRAPHICA PLATINO BRASILEIRA.

The adjourned general meeting of the above Company was held on Friday, the 18th inst., at the offices, No. 66, Old Broad-street, under the presidency of Mr. John Pender, M.P.

Mr. W. Payton, the Secretary, having read the notice calling the meeting, read the minutes of the last meeting, which were approved by the present meeting, and signed as correct by the Chairman.

The Chairman then reminded the meeting that the object of the adjournment was to receive the report of the directors, and to receive a report from the Committee appointed to report upon the transfer of the Company's property and business, effected with Brazilian law, and the constitution and Articles of Association of the Company. It was most difficult to work the Company as it was now constituted.

The Secretary then read the report of the final committee—Sir James Anderson, and Messrs. J. Reuben and C. Burt—who stated inter alia, that the Committee had examined the accounts of the Company, and had had several meetings with Messrs Gwynn, Hicks, and Co., and to the latter firm was due the compiling between them and Messrs. Hicks, Herman and Co., as agents for the Company, was carried out by an order of the court in the action, by which the accounts were referred to the arbitration of Mr. Turquand, and the investigation before him was still pending when the failure of Mr. Ernest took place, and had not since been continued. They were informed by the accountants that all expenses previous to the 31st of March, 1869, were charged to capital account, and that all expenses since were charged to revenue, except such as were clearly chargeable to capital. They approved this arrangement. When the statutes were originally framed the issue of part of the capital in the form of debentures did not appear to have been contemplated, and it was doubtless anticipated that the profits of the Company would enable the directors to pay them off. The directors had, however, very wisely kept their profits at a level much more than sufficient for the reserve fund, and, therefore, it appeared to them that the course adopted by the present directors in setting aside for the reserve fund 10 per cent. of the net earnings of the Company from its foundation, before declaring interest on the debentures, was right and prudent. They had asked the accountants for the details of the large item of £10,238 for general expenses and the £5,000 for law charges, and had been informed by the accountants that the £5,000 only of this amount had been incurred by the present directors of the Company (when acting as the committee of shareholders) and during the last six months, the charge of the remainder having been incurred during the management of the Company in Brazil. They learned from a circular issued by the Western and Brazilian Telegraph Company to its shareholders that the telegraph line from Para to Santa Catharina, including the Amazon branch, and the line from Rio Janeiro to Montevideo under the original, also that during the last twelve months 833 miles of new cable, nearly all sheathed, had been added to shallow waters, having just a moderate length in those waters which it would be necessary hereafter to renew, and that the old cable laid in deep water was in excellent condition. Having regard to the position of the Company in the gross receipts of the Western and Brazilian Company, this information was satisfactory, and they had, therefore, no hesitation in recommending the adoption of the future profits of the Company, based on the income of the last year, showing a probable net income of £7,500, after setting aside the reserve required by the articles and paying the interest on debentures. This estimate appeared to them to be a very moderate one. They recommended that the Directors' report should be adopted, and that the dividend proposed by them should be declared and paid.

Mr. Bradge then entered the meeting, and in reply to the Chairman stated that the Brazilian law required that the report of the final committee should be read by one of its members) and he considered the report as having been read by himself.

The Chairman then moved—"That the report of the final committee be approved, and that a dividend of 5s. per share, free of income tax, be declared and paid."

Captain Patt having seconded the motion, it was carried unanimously.

"Incense" are of all sons the most exacting as regards artificial light. So much have persuaded. It is not different to see how a large belt will fail. The wind is expelled example, the Leeds Town Hall, the great organ in the gallery is worked by the pressure in the town mains, and such a blower cost a uniform pressure of, say, 3 lb. on a square inch, no matter how small a consumption of gas there may be. In passing through the pipe the air might be raised to a temperature of 1,000 deg., or 1,200 deg. Hence it would be of really enormous capacity used in non-conductors, to a point at which the first pyro-hydrogen lamps, placed in actual contact with the gas, and pyro-hydrogen lamps, placed in actual contact with the gas, and so of producing the resulting light should, it will be seen, be comparatively moderate. Of what the pyro-hydrogen lamp is capable it is impossible to say without further experiments than have yet been undertaken, but it would appear that it can be adapted to the illumination of large public buildings, and possibly of streets as well even private houses. At any rate within the metropolis it should be possible to obtain a moderate quantity of air under pressure, which is the first thing needed. There are various ways in which this air may be heated; one that any required temperature and end pipe, is would not with heat enough comes the time-light may be obtained of the electric light. It may be worth while to mention experiments which have been going on for some months in Staffordshire to show that large volumes of highly-oxygenated air may be obtained for a very small cost, which if this be true then the work of the gas companies would be much facilitated.—*The Engineer.*

"A FEW EXPERIMENTS WITH THE INDUCTION COIL."

By GEO. M. HOPKINS.

In a former article* socilet directions were given for making an induction coil capable of yielding a 1½ in. spark. A few experiments will now be described which exhibit phenomena peculiar to the secondary current. The spark

FIG. 1.—PATH OF ELECTRIC SPARK OVER MICA.

between the points of the wires that extend from opposite ends of the coil turned in center is of itself interesting and beautiful. It is in fact a miniature desire of the particles of the metal. By connecting a wire with one terminal of the secondary coil, and allowing its free end to dip in a glass of water, and placing a wire connected with the other terminal near the surface of the water, a spark will be obtained from

FIG. 2.—ELECTRIC DISCHARGE OVER MICA.

rapidly from the one point to the other, giving a vivid light, and appearing altogether solid. A piece of paper or card board placed between the points is readily punctured, and the current finds its way through mica, the surface of which it will follow in various directions toward the hole through which it passes, at which point the spark is very bright.

A sheet of mica, about 4x6 inches, having upon one side a sheet of silver leaf 2x3 inches, may be used in some very

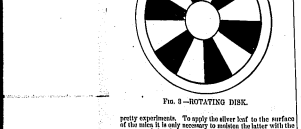

FIG. 3.—ROTATING DISK.

pretty experiments. To apply the silver leaf to the surface of the mica it is only necessary to moisten the latter with the tongue and then lay on the leaf. When the sheet of mica, thus prepared, is placed between wire discs, from ¼ to ⅜ inch from the rods, which are connected with the terminals

* SCIENTIFIC AMERICAN SUPPLEMENT, No. 95.

of the secondary coil—as shown in Fig. 1—the spark leaps downward in the mica surface, and then travels in a tortuous path to the vicinity of the point of the other rod in such rapid succession that the mica appears to have several sparks apparently. These sparks follow each other

PROFESSOR HUGHES ON INDUCTION.

From the criticisms which we have heard, there appears to be an impression amongst electricians that Professor Hughes' paper on Induction on Air Telegraph Lines, read before the Society of Telegraph Engineers on March 12th, and treated by us in our last number, does not bring forward any new solution of the induction problem; his pointed out that reversed induction coils inserted at the beginning of two lines have been employed by Mr. Wilson of Chicago, and Mr. Little of New York, as well as by other electricians. But there is an important essential difference between these earlier methods and that of Professor Hughes, which a fuller study of his paper than we had time to give it before our last issue, has made clear to us. Professor Hughes' researches were of that kind which are not grasped at once from merely hearing them read over; and it is matter for regret that a special night was not set apart by the Society for the full discussion of them after members had had time to study the printed paper thoroughly. As it is, we fear that many of those present at the meeting did not understand the results submitted to them, and not understanding them, did not, of course, appreciate them. Hence it has come to pass that one of the most important and original contributions of the winter has been hurried over in neglect.

The plan of connecting reversed coils in circuit with the wires of the line, and adjusting their mutual induction so as to balance the mutual induction of the wires, as used by Mr. Wilson, is sufficient for a two wire line; but when three or more wires have to be balanced it fails. To apply it to ten wires, for example, as many as forty-five coils would be required, and even then the balance would be imperfect. This is due to the necessity of making the balance at one, any number of the ten wires may, in actual working, become primaries to the others as secondaries; in short, that all sorts of combinations of the inductive influence may take place.

Now, Professor Hughes dispenses with the need of so many coils; 1, by making the length of each coil proportionate to the length (and consequently the actual wire it stands for, and 2, by distance from each of the other coils proportionate to the distance of that wire from each of the other wires of the line; 3, by making the the other wires of the closes each circuit, also by the same act, reverse the adjusted coil which represents that wire in the arrangement of induction coils forming the artificial line. To explain this, let us consider one end of the three wires, a, b, c, in order. The first case we have is when all the three are silent or merely receiving at the end in question. Here the three corresponding coils are all in circuit in one way, some being reversed with respect to the other. If, however, a begins to signal from one end, it is necessary that the key should reverse a's coil with respect to those of b and c. Again, if both a and b begin to work it is necessary that their keys should reverse both of their coils with respect to that of c, which remains as it was. But, it may be objected that we have now the coils of a and b both in one direction, and not reversed to each other. The answer to this, given by Professor Hughes, is, that it does not matter, there need be no mutual induction between them, since, as pointed out by Faraday in 1832, but forgotten since, current induction is due to change in the magnetic field surrounding the current. If, then, the simultaneous currents of a and b were made of equal strength; they will rise and fall together when the circuits are closed without any shock to the magnetic field generating induction. We should add, that the same results may be secured by keeping the coils of the artificial line permanently in circuit and connecting up the key between the line wire and the coil, so that the current should divide, part flowing through the wire to the distant station and part flowing in the reverse direction through the coil to earth.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents.]

EDISON'S INDUCTION EXPERIMENTS.

SIR,—My attention has been drawn to a telegram from Mr. Edison, contained in your last number, in which he says:—"In my paper on induction, lately read before the Society of Telegraph Engineers, the object of that paper was, as there stated, not long and complicated, but to discuss the question generally, with a view of showing that my personal researches were there stated not to be new, and that patents myself, or belonging out patents of others; the discussion was then invited, and which will take place next week, amply sufficed for my associates to bring forth his own solution of the difficulty. Still, as I stated in my paper, I was anxious to give credit where due, and I therefore, before the reading of the paper that Mr. David Brooks, of Philadelphia, had already proposed the use of double-twisted wires, and I at once assumed credit for the idea. I learned immediately after the lecture, that Professor T. Wilson, of Chicago, had very beautifully resolved the difficulty as regards two wires by the use of coils and counter currents." Now, I have before me Mr. Edison's telegram that he also, as well as Mr. Wilson, used inductionless coils and counter currents, and that his claim would be found in patent No. 186,787, 1877. If this I was unaware, as it was not patented in England. Of the "Telephone" or "Inductive" line under the title of "Telephone," Still, if I had been aware of this claim in his telephone patent, I should have at once, as I have always done, called the date of his patent. If the question was simply limited to his patent of 1877, I should at once freely and very willingly admit that Mr. Edison might have a perfect claim to priority of invention of a single line, as proposed in his patent. But Mr. Edison has not, as I understand that his patent is exactly the same thing as my instrument I showed, amongst many others, and that this instrument I showed, and which I used for some months at his request, before Mr. Edison spoke to the compression of one line, then I freely accord to Mr. Edison the priority, and I have balanced all the fees on some relays as I supposed to do, I must beg to differ from him, and show the essential difference.

In describing the bifilar instrument in my paper, I described the line with coils at relative distances, and showed that the further the coils were from the induction, and do more harm than good. Now I also described exactly the theoretical conditions as shown in Ellis' mathematical paper showing what would not do, I therefore stated how, by fulfilling certain conditions—not one of which are mentioned in Edison's patent—a perfect electric balance could be obtained for all lines. Those conditions were too technical to fully describe here, but they may be summarized to the effect that must be reversed as instead of putting on battery or by Quintin Coils must all have a certain definite length of wire in exact proportion to that of the used upon. (2) Battery power must also be proportionate to length, so as to have equal force on each line.

There are many other details, such as question for extra cords, static change, &c. The main difficulties, however, are overcome and Mr. Edison's is, in reality, nothing more than the question of practicability and utility, that, as a simple laboratory experiment, Edison's instrument is described in English and American patents, and which I have not, but not for the rest of the many adjacent wires. Mr. Clos. I am sure you are very beautiful and superior arrangement will perfectly answer for any two lines. The arrangement I proposed compensates for all, and any other wires being all perfectly free from induction.

London, March 31st. D. E. HUGHES.

[For the present we refrain from offering any comment upon the controversy between Mr. Edison and Mr. Hughes.—ED. E.]

PROFESSOR HUGHES' INDUCTION BALANCE.

We condense from *Engineering* of March 14, 1879, the following description of Professor Hughes' induction balance:

The invention of the telephone by Professor Bell has placed in the hands of the physicist a detecting instrument of greater delicacy and sensitiveness than the most delicate galvanometer, and one which is besides to be active and convenient in use; and the invention of the microphone by Prof Hughes has supplemented the telephone for electrical research, and has largely extended its field of usefulness. So sensitive is the telephone, or perhaps we may say, so sensitive is the human ear, aided by the telephone, that vestigations of electric currents so small as to be far beyond the powers of the most sensitive galvanometer to detect, are instantly made apparent by its use, and it is found next to impossible to work the instrument for business purposes in many places during business hours by reason of the induced currents produced in its conductors by the influence of neighboring lines conveying telegraphic messages.

The elimination of the effects of induction for telegraphic working has hitherto been one of the great unsolved problems of the telegraph engineer, and several plans have been adopted whereby the evils resulting from it have been lessened, but all are far from satisfactory.

It has remained for Professor D. E. Hughes, the eminent inventor of the type printer, as well as of that still wonderful instrument the microphone, to solve the problem by which inductive currents in telegraph lines may be absolutely neutralized, and his solution of this problem is as simple as it is scientifically accurate. The whole apparatus, part of which we illustrate, consists of a few coils of wire, a telephone, a microphone, a small three-cell Daniell's battery, and a galvanometer.

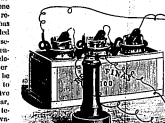

Fig. 1.

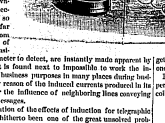

Fig. 2.

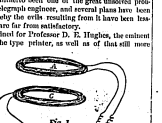
The diagram, Fig. 1, represents an experiment arranged by Professor Hughes, which demonstrates a simple case of ordinary electrical induction. A and C are two circular coils of insulated wire, of which one, C, is placed in circuit with a battery, B, and microphone, M, upon which a small clock is placed, and the other coil, A, is joined up in circuit with a telephone. Upon placing the ear to the telephone the ticking of the clock is loudly heard by the inductive currents produced in A, by the influence of the neighboring microphone currents passing through C. When the two coils are placed one against the other the sound is nearly as loud as when the telephone was included in the primary circuit, and as the distance between the two coils is gradually increased, the ticking becomes fainter and fainter, but at several inches distance the ticking was louder than the original sound emitted by the clock, and with several feet between them it remained distinctly audible. The demonstration of induction currents by means of two such rings does clock and microphone in conjunction with a battery as a simple automatic source of sound, or rather of electrical impulses, and of a telephone as the detecting instrument, forms together an exceedingly convenient arrangement, and we mention it here because it forms the groundwork of the system upon which Professor Hughes' recent experiments have been carried on. We may mention here, in passing, that this arrangement forms a beautiful way of illustrating the diminution of induction influence by destroying the parallelism between the planes of the two rings, for if either of them be slowly turned about one of its diameters, the sound heard in the telephone gradually diminishes as the angle between the planes of the two rings, for if either of them be slowly turned about one of its diameters, the sound heard in the telephone gradually diminishes as the angle between the planes of the two rings is increased, disappearing altogether at the moment that they become perpendicular to one another.



CLOCK AND MICROPHONE.

Professor Hughes placed between the coils a sheet of copper 12 inches square and one millimeter thick between the coils (gluing both coils and plate to the same earth plate), without disturbing the induction effects, in next tried the effect of introducing between the coils lumion of sheet iron; but no perceptible reduction of the induction currents could be detected. Covering each of the coils with several layers of the foil and immersing both in a vessel of ash water, with a plate of copper between them, did not diminish the induction as far as the ear could detect.

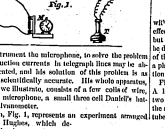


Fig. 3.

Fig. 3 represents a modification of the same experiment. A is a Daniell cell of wire having a hundred turns, its two ends being joined to the terminals of a telephone, and the wire-lengths, portion of the coil is inclosed in a heavy brass tube, H, one eighth of an inch thick. C C is a primary wire in connection with a clock microphone and battery. Upon placing the slide, B, of this coil near and parallel to the wire, C, the sounds of the clock are distinctly audible, and hardly any difference of induction influence can be directed between the influence of the currents in C on the portion of the coil surrounded by the tube and on the unprotected parts of the secondary circuit.

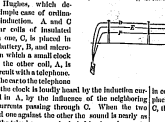

Fig. 4.

Having demonstrated that a metallic shielding or screen is altogether ineffectual for the protection of telegraph lines from the effects of lateral induction, Professor Hughes turned his attention to the question whether, although induction cannot be destroyed, it may not be neutralized or compensated. With this object in view he constructed a set of four separate insulated wires, which could be joined up at their free ends in several combinations. Joining one wire to the telephone, and one of the others to the telegraph, so powerful induction, as might be expected, took place, the ticking of the clock being heard loud and clear, but no apparent increase or diminution of the sound was produced when three of the wires were in circuit with the microphone, in the same direction, and the fourth was connected with the telephone. By joining two of the wires to the microphone circuit in such a manner that the current through one returns by the other, the inductive influence is completely neutralized, and absolute silence is the result. From this it follows that it is perfectly possible to protect a telegraph line from disturbance by the induction of its correspondents.

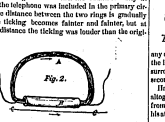

Fig. 5.

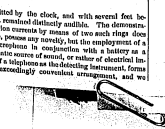

Fig. 6.

In Fig. 5, A and B represent the two coils respectively of two Professor Hughes electro-magnet, of a telegraph instrument at the receiving station, but it differs from the ordinary electro-magnets in the fact that the coil surrounding each core is connected with its own separate battery as in the usual way. An improved application of the same principle is shown in Fig. 6. The bobbin of the electro-magnet is wound with two coils of equal length and thickness. Each of these coils is connected with the battery, one through the contact-breaker at the transmitting station and the other through the line and a sympathetic relay. The current through the line and a sympathetic relay. The current through one line and a sympathetic current through the other, but the coils of the magnet are so connected to the line at the receiving station, that the positive currents traverse in coil in the opposite direction as regards the magnet core, and the negative current passes in the opposite direction, so that, by the influence of double reversal, the effect is the same as that of a single current of double the strength traversing the magnet in the usual way.

It will be seen that portion of Professor Hughes' researches which constitute the important contribution to the science of telegraphy. We have but little doubt that Hughes' induction balance, by which term we would include all instruments based upon its essential principles—will ultimately take its place side by side with Wheatstone's bridge in the history of the electric telegraph, for by its means the telegraph engineer will be enabled to eradicate from his lines the disturbing and cost-entailing effects of electrical induction. In Fig. 7, let D, E, and F represent three lines of telegraph, supported on poles and running parallel to one another; if a current of electricity be transmitted along the line D, it will induce in each of the lines E and F a current in the opposite direction, whose relative strength will be determined by the distance of its corresponding wire from the inducing or primary wire, D. Now, if at the moment of sending a current through the latter, it were possible to transmit through each of the lines, E and F, a current in the same direction as that of D, and exactly the same strength as the currents produced in the opposite direction by induction, the two, being equal and opposite, would completely neutralize one another, and although, as a matter of fact, the latter line would be exactly the same, its effects would be completely eliminated and destroyed.

Fig. 7.

At the transmitting end each of the lines is connected to a small induction coil or ring, X, Y, or Z, similar to those figured in Fig. 1, and placed one in front of the other, so as to exercise an inductive effect, the one upon the other. Now, from what has been said, it is obvious that if the coils were all similarly connected to their respective wires the effects of induction between one circuit and the other would be increased by the addition of the inductive effects of the coils being superposed upon and added to the inductive effect of the lines; but if at the moment of transmitting a current through the primary wire the two ends of its corresponding coil were reversed, then the inductive effects of the line and of its coil would be equal on the lines and coils of the other circuits and in opposite directions, and the aggregate influence would be reduced by the sum of the effects between the two inductances. By making the length of wire contained in each coil, however, proportional to the length of its corresponding line, and the number of turns proportional to the coils proportional to the mean distances of the lines from one another, the inductive effects of the coils are exactly equal to the inductive effects of the lines, and if their direction of the coils, then the problem is solved and all effects of induction are eradicated.

For the purpose of practically demonstrating the system of compensation, Professor Hughes constructed the apparatus shown to the right of the general perspective view. The five rings of insulated line wire attached to the board represent three lines of telegraph running parallel. The two coils of each of the outside pair are joined so as to form one circuit, consisting of one block coil, and the other coil, each pair representing one line of a certain length, and between them is a single coil representing a similar telegraph line of a shorter length; this difference of length in order to represent a somewhat complicated case, and to show that no matter what the relative lengths and distances apart of telegraph lines, their mutual induction may be compensated by suitably constructed and adjusted compensating coils. The compensation portion of the apparatus consists of three rings whose distances apart can be adjusted by sliding in or out the cylinder to which each of the outer coils is attached. On the front corner of the board is the commutator, consisting of six stiff elastic wires, which can be sprung against twelve brass nails, and the connections are so arranged that the battery circuit may be sent through any one of the lines, with or without the balance in the circuit, and each line can be made either a primary inductorial circuit, or a secondary line in connection with a telephone, by simply placing the commutator wires against their proper contact pins. The microphone and clock, which is the source of sound, and which is shown below, was placed in a distant room, and the direction of the currents through out the whole apparatus was under perfect control by means of the commutator to which we have referred.

PROF. EDISON'S INDUCTION BALANCE FOR TELEPHONE LINES.

On the opposite page we give a full description of Professor Hughes' induction balance—an invention for which he claims originality, and which he is receiving great credit in England. It is, however, identical in principle, and almost exactly the same in construction and arrangement as Professor Edison's apparatus, patented in England July 30, 1877, and in the United States April 30, 1878. The fact that Prof. Edison perfected the invention, patented it, and brought it into use so long before Prof. Hughes brought out his apparatus, is *prima facie* evidence that he—Edison—is the first inventor of the inductional balance.

From Edison's U. S. Patent Specification.

In telegraph lines there are very often numerous wires running in the same direction upon the poles, and it has long been known that currents passing through one or more of said wires set up inductive currents in the other wires. These, collusively, are harmless in the Morse and other systems of telegraphy; but where a wire for a telephone, acoustic, or speaking telegraph, runs parallel to or within the field of the electric influence of another wire, there are false and confusing sounds at the telephone—in some cases so much as to render it impossible to use the telephone. This is especially the case with the Edison system of telegraphy, which employs currents of high tension, and consequently induces powerful currents in neighboring wires.

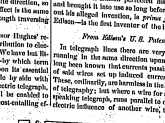

Fig. 1.

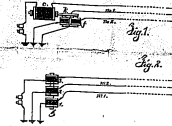

Fig. 2.

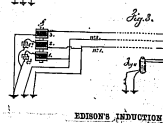

Fig. 3.

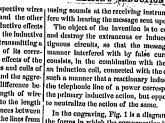

Fig. 4.

In telegraph lines there are very often numerous wires running in the same direction upon the poles, and it has long been known that currents passing through one or more of said wires set up inductive currents in the other wires. These, collusively, are harmless in the Morse and other systems of telegraphy; but where a wire for a telephone, acoustic, or speaking telegraph, runs parallel to or within the field of the electric influence of another wire, there are false and confusing sounds at the telephone—in some cases so much as to render it impossible to use the telephone. This is especially the case with the Edison system of telegraphy, which employs currents of high tension, and consequently induces powerful currents in neighboring wires.

In Fig. 1, A is an iron core, over which there are three or more coils—one for each line circuit. The coils 1 and 2 are in the ordinary or Morse circuits No. 1 and 2, while coil 3 is in the telephonic circuit. The coils are so wound and arranged, in relation to the induced currents thrown into the telephone wire by the proximity of the other wires, that they will act in the iron core, *g*, to set up a magnetism therein that will cause a powerful induced current to pass into coil 3 and telephone, equal and opposite in direction to the induced currents in the telephonic line due to the proximity of the other wires.

In cables consisting a number of wires there is not only dynamic induction, but static induction. The latter appears sooner than the former, and is of exceedingly short duration, so that magnetic impressions are not, as a rule, set up.

In Fig. 2 is shown a modification of Fig. 1 to meet this condition, which it does to a considerable extent, but not entirely. The induction coils 1, 2, and 3, are included in derived circuits from the line wires, 1 and 2, that pass to the condenser, *c* and *c'*, and to the earth. To obtain the best results, however, both the dynamical and statical induced currents must be, as nearly as possible, neutralized, so that they will circulate in the telephone wire in equal volume and opposite to those induced by proximity of the wires; and to obtain these conditions both magnets and condensers are necessary. Speaks former is set up dynamical induction currents, and the latter statical currents. If current No. 1 is opened there first appears a short wave of current due to static induction, then an interval, and then the dynamical induced current appears, which gradually dies away to nothing, when a compensation which will equalize the dynamical current will have taken that due to static induction free to circulate, and this current is continued by an induced current from a magnet, because time is required to charge and discharge the cores and the consequent production of the induced current.

Upon short circuits a coil with two or more wires, wound side by side upon a wooden bobbin is used, as shown in Fig. 4. One wire is placed in the telephonic circuit, while the others are placed in the circuits to be compensated for, and as connected therewith that the currents thrown into the telephonic coil are equal but opposite to the induction resulting from the wires running parallel.

By employing large wire, and a large quantity of it, I am enabled to obtain nearly perfect compensation, as the coils set up both dynamical and statical currents, no iron cores being used to retard the appearance of the currents.

From Edison's English Specification.

When several line wires run near each other, the wire used for the acoustic or speaking telegraph is influenced by induction, and false sounds will be produced. I counteract this tendency by placing one or more electro-magnets, A, (Fig. 5), in the circuit of the speaking telegraph, and one or more electro-magnets, B, in the circuit of the adjacent wires,

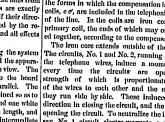

Fig. 5.

and bringing the opposite cores of B, at such a distance from the cores of A, that a certain magnetic action will be set up in A by induction in the opposite direction to the induction currents from the adjacent line wires.

By adjusting the distance between these magnets when the speaking telegraph is not in use, until there is no sound at the diaphragm from the induction currents, then these currents will be neutralized, whether strong or weak.

Les Mondes calls attention to the success with which M Baxel, a merchant of Montargne, near Blois, is cultivating the truffle. He is in a position at present to furnish thousands of these fungi, of excellent quality, at about 70c. each. He suggests that vines destroyed by phylloxera be replaced by truffle yielding oaks where the soil is calcareous or argillo-calcareous; the would be a means of recovering from the loss sustained. The products would be quickly realized, for M. Baxel has oaks six, seven, and eight years planted, which already yield truffles.

37

MASSON-HISTORICAL CURIOSITY.—According to the recent researches of Count De Rinieri, if an iron wire or core bound with a coil be shifted in the direction of the current in front of a magnetic pole, a series of induced currents in the same direction will be produced, succeeding each other, while the movement lasts, that is from the end of the wire; but this position of the coil upon a ring entirely envelopes the ring, so that in this case the two opposite parts of a single inducing pole, and as the coil is wound in a different direction, it is relative to the one resultants corresponding to the neutral lines, the induced currents produced would be contrary in direction. For that reason M. Gramme has been obliged to divide the helix circuit by a diameter, and to connect them: in the induced currents in the two halves of the ring, as 90 to 90, of those which would result if the machine are made coils induced before the inventor, (2) by those which, are determined by the intersection of polarity of the iron ring; but the effects are the same, as all those halves, dimensions and constant pulsations. (Signed) [illegible]

EDISON'S INDUCTION DEVICES.—We have received from Mr. Edison, a copy of his United States Patent No. 203,329, dated April 30, 1878. It describes several modes of overcoming for the induction of neighbouring working circuits, or telephone line, by inductors, condensers, and condensers in circuit, his method differs from that of Professor Hughes; we have described the latter in recent numbers, by placing in the ends of the coils, presenting coils in the circuit by the signalling key or other part of Signalling key, his method not being specially designed for the protection of telephones only, but with ordinary telegraphic apparatus, Mr. Edison, however, does not confine his plans to telephone circuits. Another point of distinction between his methods and that of Professor Hughes, is the location of the induction coils, Professor Hughes arranges his coils with the receiver itself, their position, in connection with each other, and length of wires. We cannot describe the actual dispositions of the line of his plan, as Mr. Edison has not yet arrived at final of Professor Hughes' preliminary [illegible]

PROFESSOR BELL ON INDUCTION.—Touching the reference made to the related wire plan for overcoming the induction in connection with the telephone Induction Compensator, Professor Bell writes to correct the statement that the same method had been "already" patented by him. He says, "I presume from this that your informant has been misled from a letter originally published by Mr. Brooks in the *Philadelphia Times*, charging me with having obtained his idea through the medium of a journal friend, and with having subsequently patented his invention as my own. In England, I have made no reply to this letter, which has not been so extensively copied as the original charge, I showed that Mr. Brooks labored under a misapprehension as to the date of a patent, instead of being November 20th, 1877, as he would be inferred from Mr. Brook's statements, the actual date is November 20th, 1877. I intend publishing shortly to the American Academy of Arts and Sciences a paper on the induction coil, describing the results of experiments in England, a copy of which I will forward when it has been published. Professor Bell the author of his telephone of hearing, Professor Hughes' beautiful induction coil, Professor Bell's induction compensator on the American Exchange telephone lines. Am 79

INDUCTION UPON TELEGRAPH WIRES.

[16201.]—In your last number you publish the specification of Mr. Edison's American patent relative to a new plan for induction upon telegraphic lines, and with which I entirely concur in regards to that there are some points of similarity between the remedies proposed in my late communication inserted at the Patent Office, Society, on "Lateral Induction upon Telegraphic Wires"), and the specification of Mr. Edison.

At the time of the reading of that paper I was unaware of any remedies having had been in the matter, though immediately afterwards he sent a telegram referring to the application for the patent. Similar I at once obtained, and found that its objects were entirely different to those proposed by myself, consequently the original means differed, according to the object we had in view.

Mr. Edison's remedies for London were publicly invited by myself to discuss the subject at the discussion of the paper held there, but no one then appeared, and Mr. Edison's claims have not yet brought forward except by myself, when I further explained the essential difference to those fully capable of understanding the subject, it hardly fair now to report the remedies upon a technical subject resulting special knowledge of telegraphy, except in those journals specially devoted to telegraphy.

MECHANIC AND WORLD OF SCIENC

The use of counter-induction by neutralising either visible or dynamic currents is not new, nor can it be by either Mr. Edison or by myself, as it has been employed in France since 1868, and also in duplex working for many years.

The object of Mr. Edison's patent was to neutralise the induction upon a single wire. This he has done by means of all the end.

Mr. Gee Wilson, of Chicago, by a very superior method to that of Mr. Edison, produced completely any two wires without injury to the remaining wires.

To accomplish, I proposed contacts all wires, connecting the matter what material and equally proportion the inductive influences of the adjacent wires.

In order to accomplish this, it required what exactly the special features of my own invention, and what transforms it into the question *from failure to success*, viz.—

1. The coils must be reversed at the instant of putting on battery, and as instantly restored to normal condition.

2. The coils must have all a certain definite length of wire to exact proportion to that of the line upon which it is used.

3. The battery power must also be proportionate to the length, or no balance need form upon.

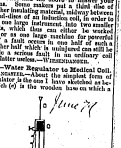
Now each of these conditions is vital, and in the specification of Edison it stated any coil each being different, to suit any line. The objection to this is obvious, as the slightest difference in the length of the coil, the balance cannot be, or believe Mr. Edison's object is of too technical a nature, not interesting to the general public, which I have to the special telegraphic journals.

Should you think this paper will be fed worthy of a place in your valuable journal, which I have long been a subscriber.

D. E. Hughes.

[20200.]—Water Regulator to Medical Coil. You would not find the above to answer your expectations. Some makes put a third disc of metal between the insulating material, midway between the two end discs of the induction coil, in order to divide its one large instrument into two smaller instruments, which then can be worked either separately or as one large machine for powerful effects. If a fault occurs in one half of such a coil, the other half which is unaligned can still be used, while a serious fault in an ordinary coil necessitates its later undue.—WIMSHURSTER.

[20200.]—Water Regulator to Medical Coil. —W. Lancaster.—About the simplest form of water regulator is the one I have sketched at below, in which (c) is the wooden base on which a

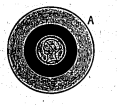


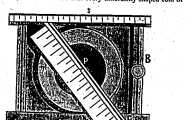
metal plate is screwed, containing a piece of brass tube in which is fitted the glass tube (f), on the top of the glass tube is another piece of brass tubing into which a cotton has been soldered, through which the brass rod (g) slides freely. The lower part is connected by a wire to the binding screw (F), and the upper part by a wire to the screw (B) for the glass tube is to be partly filled with water, and the position of the rod (g) regulates the strength of the current.—W. J. Lancaster.

ASSAYING BY INDUCTION.

In describing his new induction balance to the Royal Society (see TELEGRAPHIC JOURNAL for June 1), Prof. Hughes demonstrated its extreme efficiency as a means of assay for metals; and Mr. Chandler Roberts, F.R.S., the chemist to the Mint, has been much employed of late in testing its capacities in this direction as a measurer of the proportions of alloy in coins. In order to assist Mr. Roberts in his determinations, Prof. Hughes has introduced a novel mode of using the balance, which gives the instrument a great range of sensitiveness, and renders it capable of detecting one part of alloy in, at least, ten thousand parts of basic metal, a delicacy which far exceeds any known process of chemical analysis.

This modification of the balance will be readily understood by anyone who has read an account of the latter, by referring to the accompanying figure, where A represents the pair of coils, or induction pan, of the balance on which the coin to be assayed is placed, as shown, and B the other pair of





THE INDUCTION SCALE.

coils, framed round for steadiness, and fitted with a scale for measuring the disturbing effect on the balance of the coin placed in A. Formerly, the disturbing effect of a coin placed in A was obtained by rapidly transferring the telephone from the secondary circuit of the balance to the secondary circuit of a sonometer, and adjusting the sonometer until it gave a disturbance which to the ear seemed equal in loudness to the disturbance caused by the coin on the balance. The reading of the sonometer was then taken as a measure of the inductive power of the coin. An improvement on this method consisted in comparing each coin with a standard placed in the other pan of the balance B, and estimating the *difference* between them by means of the sonometer in the same way. But it is obvious that both of these methods are inferior to one which does not trust to the discriminating capacity of the ear, but which, like the Wheatstone bridge test of resistance, depends upon getting a balance or zero of sound.

This balance is got by means of a sliding scale of metal S, which is moved across the top of the measuring pan of the balance A. There are two elements in this scale which determine its power to produce a balance, namely, its width and its thickness. The width of metal appears to balance the intensity of the induction currents produced in the disturbing coin; and the thickness their quantity: but as the inquiries to be varied. The scale is, therefore, made of a uniform width a little over half the diameter of the coin; but it increases in thickness at a regular rate per unit of length, so as to give a mass-gradient. It is composed of zinc, which is a homogeneous, and not readily rusted metal, intermediate in inductive properties between copper above and bismuth below; and for measuring the whole series of metals, the thickness is made to increase at the rate of 1 millimetre in 5 centimetres length. It will be seen, however, that by taking a scale in which the slope of thickness is faster, say 1 millimetre in 50 centimetres length, a much higher degree of sensibility will be obtained in the balance. Such a scale would be requisite for assays of fine gold-silver alloys.

A straight guide G, is used to fix the direction of the scale as it is slid across the top of the coils in A. But it is found that every differently shaped coin or

band. This zero point can be d, for a millimetre or two to ent to cause a faint sound in to the zero is got, the scale is n, and the value obtained is an

I

LA LECTURE AU SON EN CAMPAGNE

Il y a des cas où l'appareil connu sous le nom de « *Parleur* » est appelé à rendre de grands services, même après la téléphone dont l'usage, sur les lignes de quelque longueur, n'est pas encore démontré.

Par exemple, en campagne, dans certaines éventualités, quand on ne peut s'embarrasser d'un matériel encombrant, où, suivant l'expression d'un publicistes, il est quelquefois nécessaire de réduire « *l'outillage du télégraphiste au bagage du philosophe* » (1), pour desservir des postes volants et provisoires, quand il faut un appareil commode et portatif pour dépêches et interrompre ses transmissions.

Mais on n'a pas toujours sous la main un personnel fugitifs.

C'est pour obvier en partie à cet inconvénient, amoindrir les difficultés de cette lecture *pénible* pour quelques-uns, que je propose le moyen élémentaire suivant [2] :

Le parleur est à peine modifié par l'adjonction d'une colonne métallique J, dont la borne C reçoit un fil de cuivre G, qui communique intérieurement à condensateur, avec laquelle il est constamment en relation. A l'armature du parleur, et solidaire de son mouvement, est attaché un deuxième fil conducteur mu qui a pour but de compléter le circuit d'une pile P; destinée elle-même à actionner la bobine toutes les fois que, le commutateur de celle-ci étant disposé pour laisser passer le courant, l'électro-aimant A attire l'armature B. Les extrémités polaires du fil induit, reliées aux bornes B'' et B''', sont terminées en f et f' par deux fils de platine aboutissant à un tube Geissler III''. Dans la position de repos du parleur, lorsque aucun courant ne traverse la ligne, le circuit de la pile P est par ce seul fait interrompu ; toute trace d'induction disparaît dans la spirale S qui ne saurait, en cet état, influencer le tube. En supposant au contraire le parleur en fonction, c'est-à-dire l'armature B ramenée au contact par un courant de ligne, le circuit se ferme, la bobine inductrice PD, parcourue par le courant local, agit sur l'hélice S, et malgré l'étrangeté du phénomène, le tube est aussitôt allumé par un flot de lumière plus ou moins prolongé, dont le degré d'intensité ou de continuité dépend de la durée du contact de l'électro-aimant et de son armature.

Ainsi s'établit entre le point et le trait une différence appréciable, assez sensible, qu'il est facile de reconnaître après quelques jours d'exercice.

Si l'oreille perçoit mal ces sons, les yeux peuvent en contrôler et rectifier immédiatement la valeur.

L'expérience faite avec une bobine semblable à celle dont on voit le plan grandeur naturelle à la page précédente, et avec un parleur ordinaire, a confirmé ces prévisions et donné des résultats satisfaisants.

L'élément employé était un couple *Guiffe* du plus petit modèle, charbon et zinc, avec solution de bichromate de potasse.

Dans le cas de coupure d'un fil ennemi, opération pénible qui a lieu généralement la nuit, le bruit est mauvais auxiliaire qu'il est prudent de diminuer, nouvelle tes-attitude par un réglage approprié devient inutile, pour faire place au mode de perception qui vient d'être indiqué : la lumière, conséquemment protégée des indiscrétions.

Le même dans supprimée.

Le même dans son ensemble, le rôle de la palette, que je l'indiquerai, ne borne à ouvrir ou à fermer l'unité d'une pile Daniell capable au besoin, par disposition spéciale, de produire un double effet récepteur et de transmission.

La lumière lorsque ce système permet au télégraphiste inhabile ou même à un soldat connaissant l'alphabet Morse, d'interpréter les signaux d'un télégramme.

L'induction au parleur de la machine d'induction Ruhmkorff, au poumon absent lui enlever son caractère utilité et sa principale qualité; mais ces deux instruments seront encore plus portatifs qu'un seul appareil deux emplois combiné aura toujours addition, 2° la lecture immédiate.

Les paroles pas un temps souvent précieux sont-il faut saisir ou donner, pour ainsi dire au ordre important à déchiffrer une handelement des à multiples, telles qu'un réglage insuffisant, un du mouvement d'horlogerie, une rupture d'une aux mécaniques, entraverraient momentanément fidélité de reproduction.

Ingénieux repos, application curieuse des effets aux des courants d'induction, fait naître l'idée système de télégraphie optique qui rendrait ce possible, plus simplement que ne l'a imaginé officier de marine d'un grand mérite, ses idées sur la signaux entre les différents de la même escadre.

E. NAVES
Employé du Télégraphe à Bordeaux

(2) « Le condensateur *dérive* les deux électricités de « l'extra-courant, en les rétablissant sur ses armures, et « finalement exalte l'action inductrice totale et les fonctions « des extrémités du tuboleu. » (*Traité d'Electricité*, t. II, Guevarez).

JUNE 6, 1879.

AN INDUCTION BALANCE.

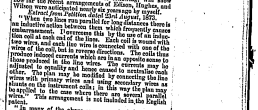
TO THE EDITORS OF ENGINEERING.

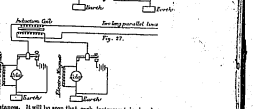
SIR,—I have been much surprised to learn that in none of the letters which appear had been written on the subject of the neutralization of dynamic inductive currents, which, when they are sensitive have any sensible effect on the line. Each call is wound with wires of the coil, but the two wires in connected with one of the poles of the battery, the other with the telephone. The coils thus produce induced currents which are in opposite sense to those produced in the line wire, and which can easily be adjusted to equality and hence caused to neutralize the effect. The plan may be modified by connecting the line wires to the primary wires and using secondary wires as shown on the accompanying coils; in this way the plan may be applied to the case where there are several parallel wires." This arrangement is not included in the English patent.

In many of the above arrangements inductive coils and electro-magnets are employed for the production of induced currents. I find that it is only necessary to use at least 50 per cent. of the strength of the induced currents may be obtained from the coils by winding the two electro-magnets together in the ordinary manner, but using for each instrument a soft iron armature to their axes form, as shown, in the case of Indicator Coils, each of the electro-magnets is wound with primary and secondary wires, and the primary wires are so connected as to form alternate pairs.

Extract from Patent dated 7th *November*, 1873.

"Finally, Fig. 26 will show the arrangement spoken of in my petition for procuring or constructing the inductive coils between the wire resting parallel for four





distances. It will be seen that each instrument is placed in the circuit of one of the induction bridges; this is done in order to counteract the electro-magnetic retardation caused by the line currents instead of by the local electro-magnets. Simple electro-magnets might be employed as in Fig. 27, but with less effect."

Yours truly,
C. W. WARREN.

ARUNDEL, May 5, 1879.

P.S.—The paper in the "Journal of Telegraph Engineers" gives an arrangement similar to this, the two wires of the induction coil being shown on the relays.—C.W.W.

[illegible] Inventive Life 1879

DANIELL.

[2097.]—Induction Coil.—Use the primary two layers No. 16 cotton covered wire, the intermediate of three layers No. 24 cotton covered wire, which is more than better of the paper; the sheets of thick alternately pasted on each side, and the two ends connected to the two pillars of the contact-breaker.—E. H. HILLS.

[2096.]—Intensity Coil.—The condenser will be found to consist of 36 or 38 silk-covered wire; for the secondary coil, calculate the space between primary should be made up of about 36 layers of thinfoil, and secondary 72 layers of paper, each layer being separated from one another and paper between each of the layers of secondary; the latter by a piece of paper previously soaked in paraffin before winding the secondary on. The finished bobbin should be placed in paraffin before winding the secondary on. The core should be connected to the binding-post of the secondary coil, and the other end of secondary to the binding-post marked sec. say, No. 2; the latter between each succeeding coil. To the end coming out from the centre of the bobbin paraffined paper should be which is connected to binding-screw on the terminal. Full instructions and take battery cells. Have a second bottom to the stand good coil. Do not put too much paraffin, but there be just sufficient to handle every wire from its neighbours.—W. J. LANCASTER.

[2095.]—Induction Coil.—For making a coil to give 1in. spark you want 1lb. of silk-covered wire, No. 36, for the primary, and 1lb. of No. 40 silk-covered for the secondary. Make the primary coil first, by winding over a paper tube 2in. in diameter and 8in. long. Fix the tube with soft iron wire, No. 22, well annealed, in the centre, with a piece between primary and secondary, and wind from 2in. to 1in. of No. 40 over the primary coil, and put in the condensing tube, best tinfoil (generally used) it is to match the size of your box. Then put the primary coil over the other, so that the 1in. of No. 40 will be between the 2in. and 3in. Then add the foil, 1in. wide, to the right side, and put a piece of paper over it. Then wind on the secondary coil, which is waxed and paraffined wire over each piece of tinfoil. Be careful in winding pieces on the right sides together, and connect wires from the vibrator of your contact breaker. The finish ends of the condenser to the same way, and connect same with the platinised screw-point.—WIRENGARDEN.

[2094.]—Induction Coil.—Don't use the iron wire for core, but use the best charcoal iron wire.

The condenser is quite large enough, if carefully done, I should not go beyond 12in. for diameter of the primary. The primary will do well but I prefer three layers when wound nicely; then put the second for primary into melted paraffin and leave it till the air all right. The thumbs will do well with the secondary, but not quite so good. The second I would wind on two bobbins, one each side. You will find this easier to wind, and better than having both together. These are simple, and have two cheeks 2in. between the cheeks, and 1in. between bobbins. In preference to wax I would use beeswax and resin, and put under the head of insulation. The battery should be two pints, and through the whole I would prefer to vary decant upon the coil working well. The condenser is not almost right in quantity for spark, but not when the whole coil is built up and used. If you have not got a good spark, you will be able to get a good one by adding 1in. spark, and with all in good order you will be able to reach from 6in. to 8in.—W. J. LANCASTER.

[2093.]—Induction Coil.—The plan of winding a great number of separate sections is a very good one; it has been used before by Mr. Apps, of the Strand. When your instrument is completed you ought to get nearly 9in. sparks with 6—E. H. HILLS.

[2092.]—Induction Coil.—Wire, No. 10 is decidedly too thick for the primary bobbin. The diameter of the size you are making. No. 36 would have been the right size. You ought to get a spark of 2in. at least with 2lb. of No. 36 secondary. The finish ends of each section of the secondary should be connected to the separate terminal screws. You then can work each section separately and find out and record the best way to use your battery.—WIRENGARDEN.

[illegible] You will find directions and

[2091.]—Intensity Coil.—The condenser is made up of sheets of thick brown sheets of parchment two; then you can wind three layers No. 36 silk-covered wire, then a layer of cotton-covered and then get a much thicker spark; for the secondary coil you want 2lb. of No. 36 or 38 silk-covered wire; be sure and calculate the space between primary should be made up of about 36 layers of tinfoil, and secondary 72 layers of paper, each layer being separated from one another and paper between each of the layers of secondary; the latter by a piece of paper previously soaked in paraffin before winding the secondary on. The finished bobbin should be placed in paraffin before winding the secondary on. The core should be connected to the binding-post of the secondary coil, and the other end of secondary to the binding-post marked sec. say, No. 2; the latter between each succeeding coil. To the end coming out from the centre of the bobbin paraffined paper should be which is connected to binding-screw on the terminal. Full instructions and take battery cells. Have a second bottom to the stand good coil. Do not put too much paraffin, but there be just sufficient to handle every wire from its neighbours.—W. J. LANCASTER.

[2090.]—Vibrating Wire and Coil.—To Mr. LANCASTER.—Your model of Bright's spiral is not quite right; in the first place, use No. 22 wire instead of No. 16, and at least 30 to 40 coils, about 1-16th of an inch from being about 1-32th to charge, the top to a binding-screw, and the bottom to the bottom to just dip into the wire, the latter making the current from the Bunsen or battery, the current from the coil readily. Of course, the spiral will vibrate without a condenser to the contact; if you do it will not answer the purpose. In that case, if you do, it will be very, very small. You should have a coil to 7 inches of silk-covered wire, the other two of insulated wire. Then follow the same directions as named above. Of number of wind one pound is more accurate as described in the book referred to this will give a good inch spark. The condenser your intended to be used for Ruhmkorff to be charged and used for, charging the wire will packed into that space.—W. J. LANCASTER.

[illegible]

[2089.]—Induction Coil.—Ib. No. 16, silk-covered, 1lb. 16oz., primary, 1lb., No. 36, silk-covered, 1lb. 8oz. 2lb. 8oz., used for the condenser thirty sheets of foil, 6in. by 4in. The condenser in core would be comparatively useless.—E. H. HILLS.

[2088.]—Induction Coil.—To make a coil to give 1in. sparks, you want 1lb. of silk-covered wire, No. 36, for the primary, and 1lb. of No. 40 silk-covered wire, No. 36, for the secondary. The pieces of foil may be 12in. by 4in., or more you want 12lb. of insulated wire, No. 22. The box should be 8in. by 12in.; the coil 8in. long; the core 6in. by 1in. 6in. The primary coil should be wound in two layers, No. 16, well insulated. The insulation may be made of paper well soaked in melted paraffine wax or of guttapercha thin.—WIRENGARDEN. [illegible]

[2087.]—Induction Coil.—The plate for winding the coil of induction coil is made by simply fixing a small cup-wheel on the spindle which carries the coil, and a bigger one on a slotted tube acting on the iron bar which by means of a screw-thread on the axle to advance in a bearing, and thus the wire through which the wire passes. The core should be 1in. less than the coil the wire will advance as much as the thickness of the wire. There is no difference in the size of wire for horizontal and that of the vertical contact-breaker. Both are good. Your condenser is all right, and a good Ruhmkorff battery, and coil will have no bad box. By 1in., will work, the coil to your satisfaction.—WIRENGARDEN. [illegible]

[illegible] QUESTIONS.

L'appareil Volta faradique de Gaiffe (torpille).

L'APPAREIL Volta faradique de Gaiffe se compose: 1° d'une pile de deux éléments du système Marié-Davy et bi-sulfate de mercure; 2° d'une bobine de Ruhmkorff M; munie d'un marteau interrupteur commun aux bobines de Ruhmkorff ordinaires. Tous ces organes sont renfermés dans une boîte ebénoque A B C D dans laquelle nous voyons : les deux éléments de pile I; une cuiller en caoutchouc servant à doser la quantité de bi-sulfate de mercure nécessaire au fonctionnement de la pile; un flacon K contenant une provision de bi-sulfate de mercure; une pince élastique qui porte les extrémités des fils inducteur et induit et en laquelle viennent s'attacher les réophores ou conducteurs de la pile; N est un manipule ou manche destiné à servir de porte-éponge; P un levier interrupteur au repos que l'on imprime suivant la ligne pointillée P, pour mettre le trembleur automatique Q en vibration; R est la tête du tube graduateur dans laquelle est enfermé le noyau de fer, et que l'on tire plus ou moins, suivant que l'on veut modifier l'intensité du courant; S, sont des conducteurs ou pièces en boule, en olive, en pinceau, que l'on fixe à l'extrémité libre des réophores pour les porter, sur les parties de l'organisme qui doivent influencer les courants.

Comme on le voit, cet appareil est tout à fait simple; sa boîte n'est pas en tout plus grosse et plus longue qu'un livre ordinaire et on peut dire que le praticien muni de cet appareil a l'électricité en poche. C'est l'un de ceux que l'on appelle communément torpille à cause des excitations et des secousses nerveuses qu'il produit et qui sont comparables, sauf l'intensité, à celles que détermine l'introduction du poison appelé torpille.

C'est au médecin qu'appartient le soin de déterminer quelle nature de courant pour supporter le malade, courant induit ou courant inducteur, courant né dans le petit ou dans le gros fil, ou bien les deux courants réunis. Le petit appareil que nous venons de décrire peut donner à volonté l'un ou l'autre de ces deux courants

THE INDUCTOMETER.

Wurz Professor D. E. Hughes brought his beautiful induction balance before the Royal Society more than a year ago, he pointed out, among other applications of the instrument in research, how it could be used in making electrical measurements after the manner of the Wheatstone balance. The adaptation of the balance to this purpose has been very efficiently managed by Dr. O. J. Lodge, who exhibited his arrangement, which he terms an inductometer, before the Physical Society during its last session. It is to be understood that Dr. Lodge does not claim any novelty for the apparatus beyond its particular form, and one or two details of its construction. The inductometer is, in fact, a modified inductive balance fitted for electric testing. The testing principle of the induction balance, as our readers are aware, consists in causing an intermittent electric current to circulate in a primary coil or coils which induces corresponding currents in secondary coils placed near. These induced currents are passed through a telephone and observed by the continuous hum or noise which they make in the ear. The application of the telephone to electric measurements in this way, instead of a galvanometer, was early foreseen by its inventor, Professor Graham Bell.

The inductometer, as will be more readily understood by reference to Fig. 1, consists of a primary

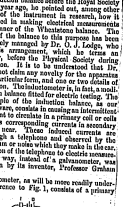


FIG. 2.

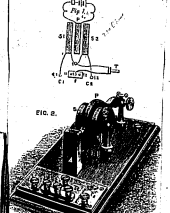


coil P, in which is circulating the current from a battery B, which may be either one or two Grove or other cells, interrupted rapidly by a clockwork make and break" key K. Two secondary coils S, S, are placed very near the primary one on each side. The primary coil is of fine copper wire (No. 30), and has a resistance of about 32 ohms, which is a little less than the joint resistance of the battery and the interrupter. The primary is permitted a slow adjusting motion to and fro by means of a screw. The secondaries, which are fixed, are made of fine wire, each having a resistance of some 270 ohms, and it is very important that they should be precisely equal in all respects.

The primary with its battery circuit may be considered the electromotive source of the apparatus. The two secondaries constitute two arms of the induction balance, and their ends are led to terminals f_1, f_2, f_3, f_4, by means of which the other two arms of the balance and the telephone connections are made. The telephone T is connected between the terminals f_1 f_3. The gap C_1 between the terminals f_2 f_4 is filled up by one of the condensers or resistances to be measured, and the gap C_2 between f_3 f_4, with the other, thus completing the four sides of the Wheatstone balance, with induction coils instead of resistance coils, as ordinarily, and with a telephone instead of a galvanometer in the "bridge" wire. Fig. 2 presents a general view of the apparatus, as made by Mr. Groves.

If C_2 and C_1 (the electric quantities to be compared) are the capacities of condensers or insulated wires, such as submarine cables, there will be no sound heard in the telephone, for the induced current in one side of the balance will neutralise that in the other. Hence the arrangement furnishes a ready means of adjusting two condensers to equality by this well-known method of "null-testing," that is, reducing the indicator of the observing instrument or indicator to nil or zero. In this case the zero will of course be silence. When the telephone is silent the equality has been obtained; when it "roars" the balance is far out; when it "murmurs" it is getting close. In fact, the degree of loudness of the telephonic hum enables the eye, with a little practice, to judge approximately how far out the balance really is. Of course to carry out the comparison properly one of the condensers must be a standard, one of known capacity, such as the standard condensers manufactured by Messrs. Latimer Clark, Muirhead and Co., and Messrs. Elliott Brothers.

In using the inductometer for such a purpose it becomes a question whether or not the element of time will enter and prevent a good balance being got when the dielectrics of the condensers compared are of different sorts, for example glass in the one case and air in the other, or gutta percha in the one case and parchment paper in the other, as usually happens in testing submarine cables for capacity. Dr. Lodge has not, we believe, completely satisfied himself on this point yet; but he has found that with ordinary glass and air as the dielectrics, a reasonably good balance can be obtained. Experiments made by Sir William Thomson about the year 1861 demonstrated that there is little or no difference between the discharges from equal condensers having air and glass for dielectrics, during the first few quarter-second, a result which confirms Dr. Lodge's observations.

When C_2 and C_1 are electric resistances to be compared, the telephone will only be silent if they are equal not only in resistance, but in self-induction. For instance, it would be impossible to balance a coiled wire with a straight one by this means. Ordinary resistance, however, might be balanced in this way, since both coils being wound of wire doubled on itself, are practically free from self-induction. But there is little inducement to employ this method for measuring resistances, which can now be so accurately and safely done by means of the Wheatstone balance, except perhaps on board ship, during the paying out of a cable, when the galvanometer may break down or prove troublesome through bad suspension or rough weather. It may also prove useful for measuring high leakage resistances; and in any case it is convenient for the electrician to have a testing instrument combining in itself the office. Moreover it may be occasionally useful to the physicist in comparing liquid resistances, as subject to polarisation under the direct passage of the current. But it is questionable whether or not the polarisation would not vitiate the results given by it, too.

The best thicknesses for the wires of the coils in the inductometer for the purpose of comparing high resistances or such capacities as are given by Dr. Lodge as follows; the wire of the secondary coils may be as thin as one pleases, and the wire of the primary coil such that the resistance is to the joint resistance of the battery and interrupter as the thickness of the uncovered wire is to the thickness of the covered wire with which the coil is wounded, a condition which also, we may add, defines the highest efficiency of a galvanometer coil.

DURÉE DES COURANTS INDUITS

1er article (voir le n° du 1er juillet).

Les machines à courants alternatifs deuxt très-employées aujourd'hui pour la production de la lumière, il peut être intéressant d'étudier les perturbations que la durée des courants induits amène dans leur fonctionnement.

Les phénomènes qui se produisent dans ces machines sont extrêmement compliqués, et l'étude complète de toutes les actions et réactions qui constituent la transformation du travail mécanique en électricité, nous entraînerait beaucoup trop loin ; mais parmi toutes ces causes acolytes, on peut choisir les principales, établir sur elles les bases de la théorie et tenir compte de l'influence des autres à l'aide de coefficients variant avec les différentes types des machines.

Pour l'étude que nous allons faire, nous n'avons besoin de considérer que les deux inducteurs et l'induit, dont les bobines sont représentées, figure 1, coupées par un plan passant par l'axe de leur fer doux et parallèle au plan de projection.

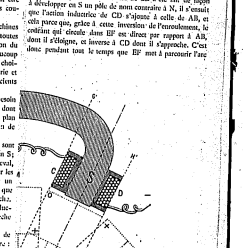
Sur les deux inducteurs AB, CD, les fils des bobines sont enroulés de façon à produire des pôles opposés en N et en S ; ils constituent en réalité un électro-aimant en fer à cheval, dont la partie montre A est ordinairement formée par les flasques des machines. L'induit EF est supposé par un moyen quelconque qui lui permet de passer aussi près que possible des pôles N,S en tournant dans le sens de la flèche.

Nous considérerons la machine au moment où les inducteurs étant aimantés, l'induit EF est sous la susdite flèche et commence son mouvement.

La bobine AB du pôle N développe dans la bobine de l'induit EF un courant de sens inverse du sien propre : cette action va en augmentant jusqu'à ce que la bord G de l'inducteur se trouve dans le prolongement du bord I de l'induit (1er position, fig. 1) ; alors commence une action contraire : la partie F du fil de l'induit s'éloignant à partir A du fil de l'inducteur et tend à produire un courant de sens inverse à celui que forment encore les parties E et B; cette action neutralisante va en augmentant jusqu'à ce que les deux lignes d'axe du fer de l'induit et de l'inducteur se trouvent dans le prolongement l'une de l'autre (2e position, fig. 1); à ce moment, la neutralisation est complète, aucun courant ne se produit. Aussitôt que cette position est dépassée, l'action neutralisante qui va toujours en augmentant à mesure que les deux bobines se recouvrent davantage, devient prépondérante; elle entraîne par conséquent le changement de sens du courant. Le premier courant que nous avons considéré était inverse de l'inducteur, celui qui vient de prendre naissance est direct.

Pendant tout le temps que le bord J de l'induit s'approche du bord H de l'inducteur, le courant qui se développe va en croissant ; il atteint son maximum quand J arrive dans le prolongement de H, parce qu'alors toutes les parties de AB s'éloignent de toutes les parties de EF ; puis le courant

Lorsque l'induit arrive dans une position telle que le bord I soit dans le prolongement du bord G de l'inducteur, un second maximum se produit, puis le courant décroît pour la raison indiquée plus haut jusqu'à ce que les axes soient dans le prolongement l'un de l'autre (3e position, fig. 1) : le courant devient nul ; puis il change de sens, etc., etc.



trouvent dans l'angle de gauche supérieur et dans l'angle opposé les différentes positions de l'induit.

EL D'ÉLECTRICITÉ

Comme l'enroulement des fils de CD a été fait de façon à développer en S un pôle de nom contraire à N, il s'ensuit que l'action inductrice de CD s'ajoute à celle de AB, et cela parce que, grâce à cette inversion de l'enroulement, le cordant qui circule dans EF est direct par rapport à AB, dont il s'éloigne, et inverse à CD dont il s'approche. C'est donc pendant tout le temps que EF met à parcourir l'arc

Si nous supposons les électro-aimants symétriquement placés en forme de couronne autour des induits, les mêmes phénomènes se reproduisent indéfiniment.

La figure 2 montre parfaitement cette succession de courants alternatifs, mais c'est tout ce qu'elle peut donner ; elle ne se prête pas à la démonstration d'un ralentissement mathématique, et c'est pour cela que nous l'abandonnerons maintenant pour employer la méthode des courbes.

Sur une ligne droite horizontale OX (fig. 3), portons des lon-

DURÉE DES COURANTS INDUITS

3e article (voir les 1er du 1er juillet et du 15 août) (1).

Pour nous rendre compte de la force nécessaire pour mettre en mouvement une machine produisant de l'électricité par voie d'induction, il importe avant tout de bien connaître les causes qui agissent comme résistance à la rotation.

Quand ces machines produisent un courant, leur marche est continuellement entravée par la production de ce courant lui-même : il s'établit entre les inducteurs et les inducteurs une série de réactions qui déterminent la formation d'ondes électriques dirigées de telle sorte qu'elles se repoussent quand le mouvement de la machine tend à rapprocher les bobines qui les produisent et qu'elles s'attirent quand au contraire elles s'éloignent. De là la nécessité d'exercer un effort continuel pour entraîner les bobines à la rencontre l'une de l'autre et pour ensuite les séparer.

Ces actions et réactions qui constituent en réalité et à elles seules la cause de la transformation de l'effort mécanique en ondes électriques, sont connues et étudiées sous le nom de « lois de Lenz ». M. Verdet les a formulées d'une façon très-précise ; voici sa formule :

« Lorsqu'un courant est induit par le mouvement relatif « d'un conducteur et d'un courant ou d'un aimant, l'action « inductrice tend à développer dans chaque élément du « conducteur un courant dirigé de telle façon que sa réaction « électro-dynamique sur le courant ou sur l'aimant inducteur « tend à produire un mouvement contraire au mouvement « relatif. » (*Conférences*, page 168, tome II.)

L'expérience a toujours confirmé cette formule, d'ailleurs, s'il n'en était pas ainsi, même dans un seul cas, il faudrait mettre en doute l'équivalence des agents physiques, et la recherche du mouvement perpétuel entrerait d'être abandonnée.

Faisons sur la figure 1 l'étude des courants qui se développent quand un induit s'approche d'un inducteur. (Voir aussi la figure 1 du numéro du 15 août, page 323).

Afin de faciliter l'explication, nous supposerons les induits constitués sur un tambour de fer dans l'section carrée ou bien de la section circulaire ordinaire, ce qui nous donnera quatre directions bien tranchées.

A B et C D sont les extrémités polaires de l'inducteur. A B est un pôle nord (austral), et C D est un pôle sud (boréal). D'après la théorie d'Ampère et en personnifiant le courant à la manière classique, c'est-à-dire en le représentant par un personnage couché sur le fil conducteur de façon que le courant lui entre par les pieds (pôle +) et lui sorte par la tête (pôle —), et regardant constamment le barreau nous aurons que le pôle austral (celui qui se dirige vers le nord) est toujours placé à la gauche du personnage, et comme conséquence de la production de ce maximum.

1° L'induit E F tend à s'éloigner de l'inducteur A B.

2° Chaque spire de fil induit tend à devenir rectiligne.

3° Toutes les spires s'attirent mutuellement, d'où tendance de la bobine à se contracter dans le sens de la longueur.

De ces trois actions la seconde et la troisième sont détruites ou doivent être détruites par la construction de la machine ; la première peut librement s'exercer si aucun effort de sens contraire ne vient empêcher la marche rétrograde de l'axe de rotation. Or, c'est précisément pour produire cet effort qu'intervient la force motrice.
